2126. *Silene*. Three-leaved speedwell (*Veronica triphyllos*) and vernal (verna) Italian viper's bugloss (*Echium italicum*), smooth rupture-wort (*Herniaria glabra*) and hairy hirsuta, English catchfly (*Silene anglica*) and other species, red sandwort (*Arenaria rubra*), &c., corn-field spurrey (*Spergula arvensis*), hybrid poppy (*Papaver hybridum*) Argemone, &c.

2127. *Ferrugineus*. Common sorrel (*Rumex Acetosa*) and sheep's sorrel (*Acetosella*).

2128. *Pasty*. Bilberry (*Vaccinium Myrtillus*), blackberry (*Rubus idaeus*), cranberry (*Oxycoccus palustris*) heath, (*Erica*) 4 sp., awl-shaped spurrey (*Spergula subulata*), official official (*Tormentilla officinalis*).

2129. *Salina*. Glasswort (*Salicornia*) 4 species, marine wrackgrass (*Zostera marina*), sea purslane (*Ruppia maritima*), sea lung-wort (*Pulmonaria maritima*), Soldanella beard-blind (*Calystegia Soldanella*), whorled knotgrass (*Melocentrum verticillatum*), sea goose-foot (*Chenopodium maritimum*) and shrubby (*fruticosa*) saltwort (*Salicornia*), whorl-leaved honeywort (*Silene verticillata*), marine sandwort (*Arenaria marina*), &c. fringed sea-rocket (*Arthrocnemum*).

2130. *Aquatic*. Marsh marigold (*Caltha palustris*), common mare's-tail (*Hippuris vulgaris*), common butterwort (*Pinguicula vulgaris*), European water-horsetail (*Lycopus europaeus*), diacious valerian (*Valeriana dioica*), marsh violet (*Viola palustris*), Valerian's brookweed (*Samolus Valeriana*), marsh thymelium (*Thymelium palustre*), square-stalked epilobium (*Epilobium tetragonum*), willow lythrum (*Lythrum Salicina*), tongue-leaved crowfoot (*Ranunculus Lingua*) and spearwort (*Filipendula*).

2131. *Very dry*. Red sandwort (*Arenaria rubra*), sheep's sorrel (*Rumex Acetosella*), wild thyme (*Thymus Serpyllum*), common acynon (*Acynon vulgaris*), field trefoil (*Trifolium arvense*).

2132. These plants are not absolutely to be depended on, however, even in Britain, and in other countries they are sometimes found in soils directly opposite. Still, the cultivated nasturtium (*Isotria medeoloides*) is almost always an indication of a calcareous soil the common coltsfoot (*Tussilago Farfara*) of blue clay the red sandwort (*Arenaria rubra*), of poor sand, and the sheep's sorrel (*Rumex Acetosella*), of the presence of iron, or of peat. The common reed (*Phragmites communis*) and the amphibious polygonum (*Polygonum amphibium*) grow on alluvial soils, which yield excellent crops if properly drained but where the corn horse-tail (*Equisetum arvense*) grows freely, it indicates a cold and retentive subsoil. The corn-field pimpernel (*Impatiens arvensis*), the corn-field madder (*Sterardus arvensis*), the corn-field groundwell (*Lithospermum arvense*), and the salad lamb's lettuce (*Valerianella olitoria*), grow on cultivated lands, where the soil is a strong black loam on a dry bottom when such a soil is wet, the clown's all-heal (*Stachys palustris*) makes its appearance. A light sandy soil is known by the presence of the purple archangel (*Lamium purpureum*) the shepherd's purse (*Capsella bursa-pastoris*). If the parsley pest (*Achillea A. phanes*) is found, the soil is rather unproductive if the corn-field spurrey (*Spergula arvensis*) grows very thick, the ground has likely been rendered too fine by the harrow, the common ragwort (*Ranunculus Jacobina*), and the cornfield curcum (*Cirium arvense*), grow indiscriminately on light and strong loams, but always indicate a fertile soil. The wall draba (*Draba muralis*) and the annual knave (*Scleranthus annuus*) grow on soils that are dry, sandy, and poor in the extreme. The spiny rest-harrow (*Oxalis spandus*) is often found on dry pasture, and where the soil is incumbent on rotten rock. The aquatic, pasty, and saline soils are almost every where indicated by their appropriate plants; a proof as we have before stated, that the climate and natural irrigation of plants have much more influence on their habits than mere soil. (*Gaillard's Compendium; Flora Brit.; London's Herbarium Brit.; Spence's Hints; Farmers Mag.* Feb. 1819, and the *Quarterly Journal of Agric.* for Aug. 1828.)

*Section. 2. Of discovering the Quality of Soils by Chemical Analysis.*

2133. *Chemical analysis is much too nice an operation for general purposes.* It is not likely that many practical cultivators will ever be able to conduct the analytic process with sufficient accuracy, to enable them to depend on the result. But, still, such a knowledge of chemistry as shall enable the cultivator to understand the nature of the process and its results, when made and presented to him by others, is calculated to be highly useful, and ought to be acquired by every man whose object is to join theoretical to practical knowledge. If it so happens that he can perform the operations of analysis himself, so much the better, as far as that point is concerned; but, on the whole, such knowledge and adroitness are not to be expected from men who have so many other points demanding their attention, and who will, therefore, effect their purpose much better by collecting proper specimens of the soils to be studied, and sending them for analysis to a respectable operative chemist.

2134. *In selecting specimens, where the general nature of the soil of a field is to be ascertained, portions of it should be taken from different places, two or three inches below the surface, and examined as to the similarity of their properties.* It sometimes happens, that upon plains, the whole of the upper stratum of the land is of the same kind, and in this case, one analysis will be sufficient. But in valleys, and near the beds of rivers, there are very great differences, and it now and then occurs that one part of a field is calcareous, and another part silicious. And in this case, and in analogous cases, the portions different from each other should be separately submitted to experiment. Soils, when collected, if they cannot be immediately examined, should be preserved in phials quite filled with them and closed with ground glass stoppers. The quantity of soil most convenient for a perfect analysis is from two to four hundred grains. It should be collected in dry weather and exposed to the atmosphere till it becomes dry to the touch.

2135. *The soil best suited for culture, according to the analysis of Bergman, contains four parts of clay three of sand, two of calcareous earth, and one of magnesia* and, according to the analysis of Fourcroy and Hassenfratz, 9316 parts of fertile soil contained 305 parts of carbon, together with 279 parts of oil, of which, according to the calculations of Lavoisier 230 parts may be regarded as carbon. so that the whole of the carbon contained in the soil in question may be estimated at about 525 parts, exclusive of the roots of vegetables, or to about one sixteenth of its weight. Young observed that equal weights of different soils, when dried and reduced to powder, yielded by distillation quantities of air somewhat corresponding to the ratio of their values. The air was a mixture of fixed and inflammable air, probably derived from the decomposition of water, either by the chemical affinities of the ingredients of the soil, or by the process of vegetation while the carbonic acid or fixed air may be absorbed from the atmosphere, or produced by living vegetables under certain circumstances. The following is the analysis of a fertile soil, as occurring in the neighbourhood of Bristol — In 400 grains, there were of water 52; silicious sand, 240 vegetable fibre 5 vegetable extract, 3 alumine, 48 magnesia 2 oxide of iron, 14 calcareous earth, 40 loss, 6. But Kirwan has shown in his *Geological Essays*, that the fertility of a soil depends in a great measure upon its capacity for retaining water and if so, soils containing the same ingredients must be also equally fertile, all other circumstances being the same, though it is plain that their actual fertility will depend ultimately upon the quantity of rain that falls, because the quantity suited to a wet soil cannot be the same that is suited to a dry soil; and hence it often happens that the ingredients of the soil do not correspond to the character of the climate. Silica exists in the soil under the modification of sand, and alumine under the modification of clay. but the one or the other is often to be met with in excess or defect. Soils in which the sand preponderates retain the least moisture, and soils in which the clay preponderates retain the most, the former are dry soils, the latter are wet soils. but it may happen that neither of them is sufficiently favourable to culture, in which case, their peculiar defect or excess must be supplied or retrenched before they can be brought to a state of fertility.

2136. *Use of the result of analysis.* In the present state of chemical science, Dr Ure observes, no certain system can be devised for the improvement of lands, independent of experiment; but there are few cases in which the labour of analytical trials will not be amply repaid by the certainty with which they denote the best methods of melioration; and this will particularly happen, when the defect of composition is found in the proportions of the primitive earths. In supplying organic matter a temporary food only is provided for plants, which is in all cases exhausted by means of a certain number of crops; but when a soil is rendered of the best possible constitution and texture, with regard to its earthy parts, its fertility may be considered as permanently established. It becomes capable of attracting a very large portion of vegetable nourishment from the atmosphere, and of producing its crops with comparatively little labour and expense. (*Dict. of Chem. art. Soil.*)

*Section 3. Of discovering the Qualities of a Soil mechanically and empirically.*

2197. The physical properties of soils, and some of their most important constituents relatively to the cultivator, may be ascertained to a certain extent by various and very simple means.

2198. The specific gravity of a soil, or the relation of its weight to that of water, may be ascertained by introducing into a phial, which will contain a known quantity of water, equal volumes of water and of soil, and this may be easily done by pouring in water till it is half full, and then adding the soil till the fluid rises to the mouth: the difference between the weight of the soil and that of the water will give the result. Thus if the bottle contains four hundred grains of water, and gains two hundred grains when half filled with water and half with soil, the specific gravity of the soil will be 2, that is, it will be twice as heavy as water, and if it gained one hundred and sixty-five grains, its specific gravity would be 1.825, water being 1000.

2199. The presence of clay and sand in any soil is known, the first by its tenacity, the other by its roughness to the touch, and by scratching glass when rubbed on it.

2140. The presence of calcareous matter in soil may be ascertained by simply pouring any acid on it, and observing if it effervesces freely. Muratic acid is the best for this purpose. Calcareous soils, magnesian soils, and clays, are, for the most part, softer to the touch than arenaceous soils. To ascertain the quantity of calcareous earth present, dry soil thoroughly, and weigh 100 grains of it, which gradually add to one drachm of muriatic acid diluted with two drachms of water in a phial poised in a balance: the loss of weight will indicate the escape of carbonic acid, which will be 44 per cent of the quantity of calcareous earth in the soil.

2141. The presence of organised matter in any soil may be ascertained very satisfactorily by weighing it after being thoroughly dried: then subjecting it to a red heat and weighing it again, the weight lost found will be the proportion of organic matter and carbonic acid gas, if there should have been any. The same object may also be attained by ascertaining the specific gravity of the soil, but with less accuracy.

2142. The presence of metallic oxides in a soil may generally be known by their colour. Ferruginous soils are red or yellow: cupreous soils, interspersed with greenish streaks, &c. Cupreous impregnations of soils are rare and the usual green matter in such soils as the green sand of English geologists, appears to be coloured by iron, which is almost the only metallic impregnation in considerable quantity in any soil.

2143. The presence of salt, sulphur, coal, &c., may be known by the absence or peculiarity of vegetation, as well as by colour and the appearance of the water of such soils. Saline soils may be distinguished by the taste: sulphureous soils by their smell when thrown on a hot iron: and the presence of coal by its fragments, which will be left after the soluble matters are removed by water and muriatic acid.

2144. The capacity of a soil for retaining water may be thus ascertained. An equal portion of two soils, perfectly dry, may be introduced into two tall glass cylindrical vessels (fig. 203.), in the middle of each of which a glass tube has been previously placed. The soils should be put into each in the same manner, not compressed very hard, but so as to receive a solidity approaching to that which they possessed when first obtained for trial. If, after this preparation, a quantity of water be poured into the glass tubes, it will subside and the capillary attraction of the soils will conduct it up the cylinders towards the tops of the vessels. That which conducts it most rapidly, provided it does not rise from the weight of the incumbent column of water in the tube, may be pronounced to be the better soil. (*Grienshewite.*)

*SECT. IV Of the Uses of the Soil to Vegetables.*

2145. Soils afford to plants a food abode and medium of nourishment. Earths, exclusively of organised matter and water, are allowed by most physiologists to be of no other use to plants than that of supporting them, or furnishing a medium by which they may fix themselves to the globe. But earths and organic matter, that is, soils, afford at once support and food.

2146. The pure earths merely act as mechanical and indirect chemical agents in the soil. The earths all appear to be metallic bases united to oxygen: these oxides have not been completely decomposed: but there is no reason to suppose that their earthy bases are convertible into the elements of organised compounds, that is, into carbon, hydrogen, and azote. Plants have been made to grow in given quantities of earth. They consume very small portions only and what is lost may be accounted for by the quantities found in their ashes, that is to say, it has not been converted into any new products. The carbonic acid united to lime or magnesia, if any stronger acid happens to be formed in the soil during the fermentation of vegetable matter, which will disengage it from the earths, may be

decomposed, but the earths themselves cannot be supposed convertible into other substances, by any process taking place in the soil. In all cases the ashes of plants contain some of the earths of the soil in which they grow but these earths, as has been ascertained from the ashes afforded by different plants, never equal more than one-fifth of the weight of the plant consumed. If they be considered as necessary to the vegetable, it is as giving hardness and firmness to its organization. Thus, it has been mentioned that wheat, oats, and many of the hollow-stalked grasses, have an epidermis principally of silicious earth; the use of which seems to be to strengthen them, and defend them from the attacks of insects and parasitical plants.

2147 *The true nutriment of plants is water and decomposing organic matter* both these exist only in soils, not in pure earths but the earthy parts of the soils are useful in retaining water, so as to supply it in the proper proportions to the roots of the vegetables, and they are likewise efficacious in producing the proper distribution of the animal or vegetable matter. When equally mixed with it they prevent it from decomposing too rapidly, and by their means the soluble parts are supplied in proper proportions.

2148. *The soil is necessary to the existence of plants*, both as affording them nutriment, and enabling them to fix themselves in such a manner as to obey those laws by which their radicles are kept below the surface, and their leaves exposed to the free atmosphere. As the systems of roots, branches, and leaves are very different in different vegetables, so they flourish most in different soils plants which have bulbous roots require a looser and a lighter soil than such as have fibrous roots plants possessing only short fibrous radicles demand a firmer soil than such as have tap-roots or extensive lateral roots.

2149 *The constituent parts of the soil, which give tenacity and coherence, are the finely divided matters* and they possess the power of giving those qualities in the highest degree when they contain much alumina. A small quantity of finely divided matter is sufficient to fit a soil for the production of turnips and barley and a tolerable crop of turnips has been produced on a soil containing 11 parts out of 12 of sand. A much greater proportion of sand, however always produces absolute sterility. The soil of Bagshot heath, which is entirely devoid of vegetable covering, contains less than one-twentieth of finely divided matter 400 parts of it, which had been heated red, afforded 380 parts of coarse silicious sand 9 parts of fine silicious sand, and 11 parts of impalpable matter which was a mixture of ferruginous clay with carbonate of lime. Vegetable or animal matters, when finely divided not only give coherence, but likewise softness and penetrability but neither they nor any other part of the soil must be in too great proportion and a soil is unproductive if it consists entirely of impalpable matters. Pure alumina or silica, pure carbonate of lime or carbonate of magnesia, are incapable of supporting healthy vegetation and no soil is fertile that contains as much as 19 parts out of 20 of any of these constituents.

2150. *A certain degree of friability or looseness of texture* is also required in soils, in order that the operations of culture may be easily conducted that moisture may have free access to the fibres of the roots, that heat may be readily conveyed to them, and that evaporation may proceed without obstruction. These are commonly attained by the presence of sand. As alumina possesses all the properties of adheiveness in an eminent degree, and since those of friability, it is obvious that a mixture of these two earths, in suitable proportions, would furnish every thing wanted to form the most perfect soil, as to water and the operations of culture. In a soil so compounded, water will be presented to the roots by capillary attraction. It will be suspended in it, in the same manner as it is suspended in a sponge, not in a state of aggregation, but of minute division, so that every part may be said to be moist, but not wet. (*Græntwaite*)

2151 *The water chemically combined amongst the elements of soils, unless in the case of the decomposition of animal or vegetable substances, cannot be absorbed by the roots of plants* but that adhering to the parts of the soil is in constant use in vegetation. Indeed, there are few mixtures of the earths found in soils which contain any chemically combined water water is expelled from the earth by most substances which combine with them. Thus, if a combination of lime and water be exposed to carbonic acid, the carbonic acid takes the place of water, and compounds of alumina and silica, or other compounds of the earths, do not chemically unite with water and soils, as it has been stated, are formed either by earthy carbonates, or compounds of the pure earths and metallic oxides. When saline substances exist in soils, they may be united with water both chemically and mechanically but they are always in too small a quantity to influence materially the relations of the soil to water.

2152. *The power of the soil to absorb water by capillary attraction depends in great measure upon the state of division of its parts*; the more divided they are, the greater is their absorbent power. The different constituent parts of soils likewise appear to act, even by cohesive attraction, with different degrees of energy. Thus vegetable substances seem to be more absorbent than animal substances, animal substances more so than compounds of alumina and silica, and compounds of alumina and silica more absorbent than car-

bases of lime and magnesia: these differences may, however, possibly depend upon the differences in their state of division, and upon the surface exposed.

2152. *The power of soil to absorb water from air is much connected with fertility.* When this power is great, the plant is supplied with moisture in dry seasons; and the effect of evaporation in the day is counteracted by the absorption of aqueous vapour from the atmosphere, by the interior parts of the soil during the day, and by both the exterior and interior during the night. The stiff clays approaching to pipe-clays in their nature, which take up the greatest quantity of water when it is poured upon them in a fluid form, are not the soils which absorb most moisture from the atmosphere in dry weather. They cake, and present only a small surface to the air; and the vegetation on them is generally burnt up almost as readily as on sands. The soils most efficient in supplying the plant with water by atmospheric absorption are those in which there is a due mixture of sand, finely divided clay, and carbonate of lime, with some animal or vegetable matter, and which are so loose and light as to be freely permeable by the atmosphere. With respect to this quality carbonate of lime, and animal and vegetable matter, are of great use in soils, they give absorbent power to the soil, without giving it likewise tenacity and, which also destroys tenacity, on the contrary gives little absorbent power. The absorbent power of soils, with respect to atmospheric moisture, is always greatest in the most fertile, so that it affords one method of judging of the productive ness of land.

2154. *Examples of the absorbent powers of soils.* 1000 parts of a celebrated soil from Ormiston, in East Lothian, which contained more than half its weight of finely divided matter, of which 11 parts were carbonate of lime, and 9 parts vegetable matter when dried at 212°, gained in an hour, by exposure to air saturated with moisture, at a temperature of 63°, 18 grains. 1000 parts of a very fertile soil from the banks of the river Parret, in Somersetshire, under the same circumstances, gained 16 grains. 1000 parts of a soil from Merton, in Essex, gained 13 grains. 1000 grains of a fine sand, from Essex gained 11 grains. 1000 of a coarse sand gained only 8 grains. 1000 of a soil from Bagshot Heath gained only 8 grains.

2155. *The absorbent powers of soils ought to vary with the climate* in which they are situated. The absorption of moisture ought to be much greater in warm or dry countries, than in cold and moist ones and the quantity of clay, or vegetable, or animal matter in soils greater. Soils also on declivities ought to be more absorbent than in plains or in the bottoms of valleys. Their productiveness likewise is influenced by the nature of the sub-soil, or the stratum on which they rest. When soils are immediately situated upon a bed of rock or stone, they are much sooner rendered dry by evaporation than where the sub-soil is of clay or marl and a prime cause of the great fertility of the land in the moist climate of Ireland, is the proximity of the rocky strata to the soil. A clayey sub-soil will sometimes be of material advantage to a sandy soil, and in this case it will retain moisture in such a manner as to be capable of supplying that lost by the earth above, in consequence of evaporation or the consumption of it by plants. A sandy or gravelly sub-soil often corrects the imperfections of too great a degree of absorbent power in the true soil. In calcareous countries, where the surface is a species of marl, the soil is often found only a few inches above the limestone and its fertility is not impaired by the proximity of the rock, though in a less absorbent soil, this situation would occasion barrenness and the sandstone and limestone hills in Derbyshire and North Wales may be easily distinguished at a distance, in summer by the different tints of the vegetation. The grass on the sandstone hills usually appears brown and burnt up that on the limestone hills flourishing and green. There is a considerable difference between the sandy soils of the east and west coasts of Scotland. All along the west coast from the Solway Firth to the Clyde, such soils are more productive than soils of a similar quality on the east coast, under the same circumstances of management. The extensive culture of potatoes for instance, and the succession of corn crops in Dumfriesshire and Galloway, would seem reduce to a state of sterility much of the best sandy soils of Roxburghshire and the Lothians.

2156. *In a moist climate* where the quantity of rain which falls annually equals from 40 to 60 inches, as in Lancashire, Cornwall, and some parts of Ireland, a silicious sandy soil is much more productive than in dry districts and in such situations wheat and beans will require a less coherent and absorbent soil than in drier situations and plants having bulbous roots will flourish in a soil containing as much as 14 parts out of 15 of sand. Even the exhausting powers of crops will be influenced by like circumstances. In cases where plants cannot absorb sufficient moisture, they must take up more mature; and in Ireland, Cornwall, and the western Highlands of Scotland, corn will exhaust less than in dry inland situations. Oats, particularly, in dry climates, are impoverishing in a much higher degree than in moist ones.

2157. *Many soils are popularly distinguished as cold or hot; and the distinction, though at first view it may appear to be founded on prejudice, is really just. Some soils are*

much more heated by the rays of the sun, all other circumstances being equal, than others; and soils brought to the same degree of heat cool in different times, i. e. some cool much faster than others. This property has been very little attended to in a philosophical point of view, yet it is of the highest importance in culture. In general, soils which consist principally of a stiff white clay are with difficulty heated, and, being usually very moist, they retain their heat but for a short time. Chalks are similar in one respect, the difficulty with which they are heated, but, being drier, they retain their heat longer, less being consumed in causing the evaporation of their moisture. A black soil, containing much soft vegetable matter, is most heated by the sun and air; and the coloured soils, and the soils containing much carbonaceous or ferruginous matter, exposed under equal circumstances to the sun, acquire a much higher temperature than pale soils.

2158. *When soils are perfectly dry, those which most readily become heated by the solar rays likewise cool most rapidly; but the darkest-coloured dry soil (that which contains abundance of animal or vegetable matter, substances which most facilitate the diminution of temperature), when heated to the same degree, provided it be within the common limits of the effect of solar heat, will cool more slowly than a wet pale soil entirely composed of earthy matter.* Sir H. Davy "found that a rich black mould, which contained nearly one fourth of vegetable matter had its temperature increased in an hour from  $65^{\circ}$  to  $88^{\circ}$  by exposure to sunshine whilst a chalk soil was heated only to  $69^{\circ}$  under the same circumstances but the mould removed into the shade, where the temperature was  $63^{\circ}$  lost, in half an hour,  $15^{\circ}$  whereas the chalk, under the same circumstances, had lost only  $4^{\circ}$ . We may also refer to the influence of black earth in melting snow as practised empirically on the Alps, and tried philosophically by Franklin and Saussure. The latter placed on the top of the high Alpine mountain Crémont a box lined with black cloth, with the side next the sun closed by three panes of glass at a little distance apart the one from the other, and found the thermometer rise thirty degrees in two hours, from the concentration of the sun's rays. (*Agriculture expérimentale* &c. tom. i. 82.) A brown fertile soil and a cold barren clay were each artificially heated to  $88^{\circ}$ , having been previously dried, they were then exposed in a temperature of  $57^{\circ}$  in half an hour the dark soil was found to have lost  $9^{\circ}$  of heat, the clay had lost only  $6^{\circ}$ . An equal portion of the clay containing moisture, after being heated to  $88^{\circ}$  was exposed in a temperature of  $55^{\circ}$  in less than a quarter of an hour it was found to have cooled to the temperature of the room. The soils in all these experiments were placed in small tin-plate trays, two inches square, and half an inch in depth and the temperature was ascertained by a delicate thermometer. Thus the temperature of the surface when bare and exposed to the rays of the sun, affords at least one indication of the degree of its fertility and the thermometer may be sometimes a useful instrument to the purchaser or improver of lands."

2159. *The moisture in the soil and sub-soil materially affects their temperature, and prevents, as in the case of constantly saturated aquatic soils, their ever attaining to any great degree either of heat or cold.* The same observation will apply to moist peaty soils, or peat-bogs.

2160. *Chemical agency of soils.* Besides these uses of soils, which may be considered mechanical there is, Sir H. Davy observes, another agency between soils and organisable matters, which may be regarded as chemical in its nature. The earths, and even the earthy carbonates, have a certain degree of chemical attraction for many of the principles of vegetable and animal substances. This is easily exemplified in the instance of alumina and oil; if an acid solution of alumina be mixed with a solution of soap, which consists of oily matter and potasses, the oil and the alumina will unite and form a white powder, which will sink to the bottom of the fluid. The extract from decomposing vegetable matter when boiled with pipe-clay or chalk, forms a combination by which the vegetable matter is rendered more difficult of decomposition and of solution. Pure silica and silicious sands have little action of this kind and the soils which contain the most alumina and carbonate of lime are those which act with the greatest chemical energy in preserving manures. Such soils merit the appellation, which is commonly given to them, of rich soils for the vegetable nourishment is long preserved in them, unless taken up by the organs of plants. Silicious sands, on the contrary, deserve the term hungry, which is commonly applied to them for the vegetable and animal matters they contain, not being attracted by the earthy constituent parts of the soil, are more liable to be decomposed by the action of the atmosphere, or carried off from them by water. In most of the black and brown rich vegetable moulds, the earths seem to be in combination with a peculiar extractive matter afforded during the decomposition of vegetables, this is slowly taken up or attracted from the earths by water, and appears to constitute a prime cause of the fertility of the soil.

2161. *Thus all soils are useful to plants, as affording them a fixed abode and a range for their roots to spread in search of food but some are much more so than others, as better adapted by their constituent parts, climate, inclination of surface, and sub-soil, for attracting and supplying food.*

BOOK V. *Of the Improvement of Soils.*

§163. *Soils may be rendered more fit for answering the purposes of vegetation by pulverisation, by consolidation, by exposure to the atmosphere, by an alteration of their constituent parts, by changing their condition in respect to water, by changing their position in respect to atmospherical influence, and by a change in the kinds of plants cultivated. All these improvements are independent of the application of manures.*

SYNOPSIS. 1. *Pulverisation.*

§163. *The mechanical division of the parts of soils is a very obvious improvement, and applicable to all in proportion to their adheaven texture. Even a free silicious soil will, if left untouched, become too compact for the proper admission of air, rain, and heat, and for the free growth of the fibres, and strong upland clays, not submitted to the plough or the spade, will, in a few years, be found in the possession of fibrous-rooted perennial grasses, which form a clothing on their surface, or strong tap-rooted trees, as the oak, which force their way through the interior of the mass. Annuals and rumen-taceous-rooted herbaceous plants cannot penetrate into such soils.*

§164. *The first object of pulverisation is given scope to the roots of vegetables, for without abundance of roots no plant will become vigorous, whatever may be the richness of the soil in which it is placed. The fibres of the roots, as we have seen (1538) take up the extract of the soil by imbibition: the quantity taken up, therefore, will not depend alone on the quantity in the soil, but on the number of absorbing fibres. The more the soil is pulverised, the more these fibres are increased, the more extract is absorbed, and the more vigorous does the plant become. Pulverisation, therefore, is not only advantageous previously to planting or sowing, but also during the progress of vegetation, when applied in the intervals between the plants. In the latter case it operates also in the way of pruning, and by cutting off or shortening the extending fibres, causes them to branch out numerous others, by which the mouths or pores of the plants are greatly increased, and such food as is in the soil has the better chance of being sought after and taken up by them. Tull and Du Hamel relate various experiments which decidedly prove that, *ceteris paribus*, the multiplication of the fibres is as the imbibition: but the strength of the vegetable, in consequence of this multiplication of fibres, must depend a good deal on the quantity of food or of extract within their reach. The root of a willow tree, as we have seen (1590), has the fibres prodigiously increased by coming in contact with the water in a river, and so have various other aquatic plants, as alder, mint, *Lymnæus thymiflora*, *Calla palustris*, *Enanthe fistulosa*, &c. but their herbage is proportionally increased unless the water be impregnated with organised remains.*

§165. *Pulverisation increases the capillary attraction, or sponge-like property of soils, by which their humidity is rendered more uniform. It is evident this capillary attraction must be greatest where the particles of the earth are finely divided: for gravels and sands hardly retain water at all, while clays not opened by pulverisation or other means, either do not absorb water or when by long action, it is absorbed they retain too much. Water is not only necessary as such to the growth of plants, but it is essential to the production of extract from the vegetable matters which they contain: and unless the soil, by pulverisation or otherwise, is so constituted as to retain the quantity of water requisite to produce this extract, the addition of manures will be in vain. Manure is useless to vegetation till it becomes soluble in water and it would remain useless in a state of solution, if it so abounded as wholly to exclude air, for then the fibres or mouths, unable to perform their functions, would soon decay and rot off. Pulverisation, in a warm season is of great advantage in admitting the nightly dews to the roots of plants. Chaptal, in his *Agriculture appliquée à Chémie*, relates the great benefit he found from the practice in this respect, to his corn crops: and shows of what importance it is in the culture of vineyards in France.*

§166. *The temperature of a soil is greatly promoted by pulverisation. Earths, Green-thwaite observes, are also among the worst conductors of heat with which we are acquainted, and consequently it would be a considerable time before the gradually increasing temperature of spring could communicate its genial warmth to the roots of vegetables, if their lower strata were not heated by some other means. To remove this defect, which always belongs to a close compact soil, it is necessary to have the land open, that there may be a free ingress of the warm air and tepid rays of spring.*

§167. *Pulverisation contributes to the increase of vegetable food. Water is known to be a condenser and solvent of carbonic acid gas, which, when the land is open, can be immediately carried to the roots of vegetables, and contribute to their growth: but if the land be close, and the water lie on or near its surface, then the carbonic acid gas, which always exists in the atmosphere and is carried down by rains, will soon be dissipated. An open soil is also most suitable for effecting those changes in the manure itself, which are equally necessary to the preparation of such food. Animal and vegetable substances,*

exposed to the alternate action of heat, moisture, light, and air, undergo spontaneous decompositions, which would not otherwise take place.

2165. *By means of pulverisation a portion of atmospheric air is buried in the soil.* This air so confined, is decomposed by the moisture retained in the earthy matters. Ammonia is formed by the union of the hydrogen of the water with the nitrogen of the atmosphere and nitre, by the union of oxygen and nitrogen the oxygen may also unite with the carbon contained in the soil, and form carbonic acid gas, and carburated hydrogen. Heat is given out during these processes, and "hence," as Dr Darwin remarks (*Phytologia*, sect. xii. 1), 'the great propriety of cropping lands immediately after they have been comminuted and turned over, and this the more especially, if manure has been added at the same time, as the process of fermentation will go on faster when the soil is loose, and the interstices filled with air, than afterwards, when it becomes compacted with its own gravity, the relaxing influence of rains, and the repletion of the partial vacuums formed by the decomposition of the enclosed air. The advantage of the heat thus obtained in exciting vegetation, whether in a seed or root, especially in spring, when the soil is cold, must be very considerable.

2169. *The great advantages of pulverisation descended Tull*, who fancied that no other assistances were required in the well-management of the business of husbandry. A knowledge of chemistry in its present improved state, would have enabled him to discover that the pulverisation of the soil was of no other benefit to the plants that grow in it than as it "increased the number of their fibrous roots or mouths by which they imbibe their food, facilitated the more speedy and perfect preparation of this food, and conducted the food so prepared more regularly to their roots." Of this food itself it did not produce one particle.

2170. *The depth of pulverisation*, Sir H. Davy observes, 'must depend upon the nature of the soil, and of the subsoil. In rich clayey soils it can scarcely be too deep, and even in sands, unless the subsoil contains some principles noxious to vegetables, deep comminution should be practised. When the roots are deep, they are less liable to be injured either by excessive rain or drought: the radicles are shot forth into every part of the soil, and the space from which the nourishment is derived is more considerable than when the seed is superficially inserted in the soil.

2171. *Pulverisation should, in all cases be accompanied with the admixture of the parts of soils by turning them over.* It is difficult, indeed, to pulverise without effecting this end, at least by the implements in common use: but, if it could be effected it would be injurious, because the difference of gravity between the organised matters and the earth has a constant tendency to separate them, and stirring a soil only with forks or pronged implements, such as cultivators, would, in a short time, leave the surface of the soil too light and spongy, and the lower part too compact and earthy.

#### SUBJECT 2. *Of the Improvement of Soils by Compression.*

2172. *Mechanical consolidation* will improve some soils, such as spongy peats and light dusty sands. It is but a limited source of improvement, but still it deserves to be noticed.

2173. *The proper degree of adhesion* is best given to loose soils by the addition of earthy matters: but mere rolling and treading are not to be altogether rejected. To be benefited by rolling a soil must be dry, and the operation must not be carried too far. A peat bog drained and rolled will sooner become covered with grasses than one equally well drained and left to itself. Drifting sands may be well rolled when wet, and by repeating the process after rains they will in time acquire a surface of grass or herbage. Every agriculturist knows the advantages of rolling light soils after sowing or even treading them with sheep. Gardeners also tread in seeds on certain soils.

#### SUBJECT 3. *Of the Improvement of Soils by Aeration or Fallowing.*

2174. *Soils are benefited by the free admission of the weather to their interior parts.* This is generally considered as one of the advantages of fallowing: and its use in gardening is experienced in compost heaps, and in winter and summer ridging. The precise advantages, however, of exposure to the air independently of the concurrent influence of water, heat, and the other effects mentioned as attendant on pulverisation do not seem at present to be correctly ascertained. It is allowed that carbonic acid gas may be absorbed by calcareous earths, and Dr Thomson considers that the earths alone may thus probably administer food to plants, but Sir H. Davy seems to consider mere exposure to the atmosphere of no benefit to soils whatever. 'It has been supposed by some writers,' he says, "that certain principles necessary to fertility are derived from the atmosphere, which are exhausted by a succession of crops, and that these are again supplied during the repose of the land, and the exposure of the pulverised soil to the influence of the air, but this in truth is not the case. The earths commonly found in soils cannot be combined

with some oxygen, some of them unite to acids; and each of them as are capable of extracting carbonic acid, are always saturated with it in those soils on which the practice of fallowing is adopted."

§175. *Aeration and repose, or summer fallow.* "The vague ancient opinion of the use of nitre, and of nitrous salts in vegetation," Sir H. Davy says, "seems to have been one of the principal speculative reasons for the defence of summer fallows. Nitrous salts are produced during the exposure of soils containing vegetable and animal remains, and in greatest abundance in hot weather; but it is probably by the combination of the azote from these remains with oxygen in the atmosphere that the acid is formed and at the expense of an element which otherwise would have formed ammonia; the compounds of which are much more efficacious than the nitrous compounds in assisting vegetation."

It is proper to observe that this reason is more speculative than experimental, and seems influenced, in some degree, by the opinion adopted by the author, that fallows are of little use in husbandry. One obvious advantage of aeration in summer, or a summer fallow, is, that the soil may thus be heated by the sun to a degree which it never could be if partially covered with the foliage of even the wildest drilled crops. For this purpose, if the soil is laid up in large lumps, it is evident it will receive more heat by exposing a greater surface to the atmosphere, and it will retain this heat for a period of unexpected duration, from the circumstance of the lumps reflecting back the rays of heat radiated by each other. A clayey soil, in this way it is said (*Farmer's Magazine*, 1815) may be heated to 130° which may in some degree alter its absorbent powers as to water and contribute materially to the destruction of vegetable fibre insects, and their eggs. By the aeration of lands in winter minute mechanical division is obtained by the freezing of the water in the soil for as water in the solid state occupies more space than when fluid, the particles of earthy matters and of decomposing stones are thus rent asunder and crumble down in a fine mould. Rough stony soils will thus receive an accession to their finer soil every winter. Soils which have been soured, sodden, or baked by the tread of cattle, or by other means, in wet weather are more speedily sweetened, as the expression is, by exposure to the sun during the hottest weather of summer, than by exposure to the frost of winter; but in summer it is contended that the drying influence of the sun and air exhausts the soil of its vegetable matter to such an extent as to counteract the good effects of extreme heating by the sun. Those who maintain this doctrine contend that the only use of a summer fallow is to admit of freeing the soil of root-weeds.

§176. *Agricultural experience* has fully proved that fallows are the only means by which stiff clays in moist climates can be effectually cleared of weeds. Supposing therefore that no other advantage whatever was obtained, that no nutritive matter was imbibed from the atmosphere, and the soil was neither chemically nor mechanically benefited by aeration, this benefit alone, the effectual eradication of weeds, is sufficient to justify the use of fallows on such soils.

§177. *Many of the objections to fallows* have arisen in consequence of the parties not previously agreeing as to what a summer fallow is. In England generally or at least formerly, a fallow was a portion of land left a year without culture or cropping, unless being once or twice ploughed can be denominated the former and an abundant growth of coarse grasses and weeds can constitute the latter. The *jachères* of the French are the same thing. In Scotland, and in the best-cultivated districts, a summer fallow is a portion of land begun to be cultivated after the crop is removed in autumn and is frequently, as need requires, ploughed, harrowed, and otherwise committed, and freed from stones, weeds, inequalities, &c., till the autumnal seed-time of the following year. It is thus for twelve months in a state of constant tillage and movement. The result is, that the land is thoroughly freed from roots of weeds; from many seeds of weeds, which are then made to germinate and are then destroyed; and from many eggs of insects which are thus hatched, but being without plants to nourish them in their larva state, speedily die. The land is also thoroughly pulverised, and the top, bottom, and middle mixed together; stones are picked out, inequalities unfavourable to surface drainage removed or lessened, and various other useful objects attained. Such a fallow can no more be compared with what usually passes under that name, than the plough of Virgil (112.) with that of Bunell.

§178. *That fallows of the common kind* are much more universal than is necessary, there can be little doubt; but there can be as little doubt that fallows such as we have described are much less frequent than they should be, and that wherever they are practised, the agriculturist's produce and profits will be found far superior to where they are omitted: turnip soils are of course to be excepted, because the preparation for that crop, on light soils, effects the same purpose in eight months, that the fallow does in twelve.

§179. *The article of fallows* is commonly traced to the idea, that land naturally requires rest as well as culture: but a want of human labour, and afterwards a want of manure, are much more likely causes. Men must very early have observed, from what took place in the spots they cultivated as gardens, that pro-

variation and measure would immerse perpetual crops in the same soil; but they must at the same time have felt, that they had neither the requisite labourers to bestow the cultivation, nor cattle to produce the manure. Hence they would find it easier to break up one piece of fresh ground after another, and after they had gone a round in this way as extensive as their limits or other circumstances permitted, they would return to where they began. As their limits became circumscribed by the increase of population, or other causes, they would return the oftener, till at last, when property became more rigidly defined, and more valuable they would return at short intervals regularly. Then it was that the necessity and advantage of working fallows would be felt, and the practice become systematized as at the present day, and from the earliest records in civilized countries. The practice of fallowing in Italy, during the time of the Romans (158.), differed in nothing from that of the same country and of the rest of Europe, at the present day and if we trace field culture among savage and semibarbarous nations, and gradually through such as are more wealthy and refined, we shall find the fallow in all its gradations, from breaking up at random, to the triennial, quinquennial, and septennial operations of the best British farmers.

#### SUMMARY. 4. *Alteration of the constituent Parts of Soils.*

2180 *The constituent parts of soils may be altered by the addition or subtraction of ingredients in which they are deficient or superabundant, and by the chemical change of some constituent part or parts by the action of fire.*

2181 *In ascertaining the composition of faulty soils, with a view to their improvement by adding to their constituent parts, any particular ingredient which is the cause of their unproductiveness should be particularly attended to if possible, they should be compared with fertile soils in the same neighbourhood, and in similar situations, as the difference of the composition may, in many cases, indicate the most proper methods of improvement. If, on washing a sterile soil, it is found to contain the salts of iron, or any acid matter, it may be ameliorated by the application of quicklime. A soil of good apparent texture, containing sulphate of iron, will be sterile but the obvious remedy is a top-dressing with lime, which converts the sulphate into manure. If there be an excess of calcareous matter in the soil it may be improved by the application of sand or clay. Soils too abundant in sand are benefited by the use of clay or marl, or vegetable matter. Light sands are often benefited by a dressing of peat, and peats by a dressing of sand though the former is in its nature but a temporary improvement. When peats are acid, or contain ferruginous salts, calcareous matter is absolutely necessary in bringing them into cultivation. The best natural soils are those of which the materials have been derived from different strata, which have been minutely divided by air and water and are intimately blended together and in improving soils artificially the cultivator cannot do better than imitate the processes of nature. The materials necessary for the purpose are seldom far distant coarse sand is often found immediately on chalk, and beds of sand and gravel are common below clay. The labour of improving the texture or constitution of the soil is repaid by great permanent advantages less manure is required, and its fertility insured and capital laid out in this way secures for ever the productiveness, and consequently the value, of the land.*

2182 *The removal of superabundant ingredients in soils may sometimes be one of the simplest and most effectual means of their improvement. It occasionally happens that the surface of a well proportioned soil is thickly covered with peat, with drifted sand, with gravel or with small stones. Extensive examples of the former occur in Shropshire, and of the latter in Norfolk. In such cases, a simple and effectual mode of improvement consists in removing the superincumbent strata, and cultivating that below. This can seldom be put in practice on a large scale, with such heavy materials as gravel or stones but some hundreds of acres of rich alluvial soil, deeply covered by peat, have been bared and cultivated in Blair Drummond moss in Shropshire an operation commenced by the celebrated Lord Kaimes *Gen. Rep. of Scot., App. v. 5*) copied by his neighbours, and continued by him and their successors. The moss is floated off by streams of water, which empty themselves in the Firth of Forth. In this river, by the winds and tides, it is cast on shore in the bays and recesses, impregnated with salt and here it engenders vegetation on the encroaching surfaces of sand and gravel. Costings of sand or gravel can seldom be removed on a scale of sufficient extent for agriculture, but have, in some instances, for the purposes of gardening. Sometimes this improvement may be effected by trenching down the surface, and raising up a stratum of better earth.*

2183 *The moss of Késherdine or Blair-Drummond is situated in the parish of that name not far from Stirling, and contains upwards of 5000 acres, 1800 of which belong to the estate of Blair-Drummond. It lies upon a bed of clay, which is a continuation of the rich alluvial soil which forms the flat valleys called Carver of Stirling and Falkirk. This vale or plain had been covered with trees, which appear to have been felled by the Romans, and this by stagnating the water added to producing the moss. This moss consists of three different strata the first, black and heavy appears to have been formed of burnt grass and gullen moss; the second is composed principally of sphagnum peat-moss, and is brown and of an elastic texture; the third is about a foot thick, and consists of heath and a little bent grass. In general these three strata occupy to the depth of seven feet. Lord Kaimes took possession of this moss in 1766, and soon after conceived the idea of floating off the moss into the Firth of Forth and exposing the alluvial soil for corn culture. After various experiments, which, however interesting, it would occupy too much room to detail, the following may be given as the result.*

2184 *Manner of floating off the moss. A stream of water, sufficient to turn a common corn-mill will carry off as much moss as twenty men can throw into it, provided they be stationed at the distance of 100 yards from each other. The first step is to make in the clay alongside of the moss, a dyke to convey the*

wall, through which the shore water is conveyed into the buckets. The other trough is hid by two stone walls that support the wheel; *d d d*, buckets, of which 30 are arranged on each side of the arms of the wheel. In all 180; *e e e* a cistern, into which the water raised by the buckets is discharged; *f f f*, wooden barrel pipes, through which the water descends from the cistern under ground.

2180. The cistern of the Blair-Drummond wheel, as seen from above (Fig. 205.) shows the two troughs into which the buckets empty themselves (*g g*), the space through which the water flows to the barrel pipes (*f f* in Fig. 204.) (*h*), the place where the arms of the wheel move (*i*) and where the float boards and buckets descend (*h*).

The buckets are filled from two side troughs (Fig. 204. *g*), which communicate with the head of water which drives the wheel, as seen at *c* in Fig. 204. (Farm Mag. vol. xviii.)

2191. *Incineration.* The chemical changes which can be effected in soils by incineration are considerable. This practice was known to the Romans, is more or less in use in most parts of Europe, is mentioned as an approved practice by our oldest agricultural writers, and has lately excited some degree of attention from the successful experiments of different cultivators. (Farmer's Magazine, 1810 to 1815, and Farmer's Journal, 1814 to 1821.)

2192. *The theory of burning soils* is thus given by Sir H. Davy. It rests he says,

entirely on chemical doctrines. The bases of all common soils are mixtures of the primitive earths and oxide of iron and these earths have a certain degree of attraction for each other. To regard this attraction in its proper point of view, it is only necessary to consider the composition of any common silicious stone. Feldspar for instance, contains silicious, aluminous, and calcareous earths, fixed alkali and oxide of iron, which exist in one compound, in consequence of their chemical attractions for each other. Let this stone be ground into impalpable powder it then becomes a substance like clay, if the powder is heated very strongly, it fuses, and on cooling forms a coherent mass similar to the original stone the parts separated by mechanical division adhere again in consequence of chemical attraction. If the powder be heated less strongly the particles only superficially combine with each other and form a gritty mass, which when broken into pieces, has the characters of sand. If the power of the powdered feldspar to absorb water from the atmosphere before and after the application of the heat is estimated, it is found much less in the latter case. The same effect takes place when the powder of other silicious or aluminous stones is made the subject of experiment and two equal portions of basalt ground into impalpable powder, of which one half had been strongly ignited, and the other exposed only to a temperature equal to that of boiling water, gained very different weights in the same time when exposed to air. In four hours the one had gained only two grains, whilst the other had gained seven grains. When clay or tenacious soils are burnt, the effect is of the same kind they are brought nearer to a state analogous to that of sands. In the manufacture of bricks the general principle is well illustrated. If a piece of dried brick earth be applied to the tongue it will adhere to it very strongly in consequence of its power to absorb water but after it has been burnt, there will be scarcely a sensible adhesion.

2193. *The advantages of burning* are, that it renders the soil less compact, less tenacious, and less retentive of moisture; and when properly applied, may convert a matter which was stiff, damp and, in consequence, cold, into one powdery, dry and warm, and much more proper as a bed for vegetable life.

2194. *The great objection* made by speculative chemists to paring and burning is, that it destroys vegetable and animal matter or the manure in soil: but in cases in which the texture of its earthy ingredients is permanently improved, there is more than a compensation for this temporary disadvantage and in some soils where there is an excess of inert vegetable matter the destruction of it must be beneficial and the carbonaceous matter remaining in the ashes may be more useful to the crop than the vegetable fibre from which it was produced.

2195. *Three specimens of ashes* from different lands which had undergone paring and

burning were examined by chemical analysis. The first was from a chalk soil, and 200 grains contained 80 of carbonate of lime, 11 gypsum, 9 charcoal, 15 oxide of iron, 3 saline matter, sulphate of potash, muriate of magnesia, with a minute quantity of vegetable alkali; the remainder alumina and silica. Suppose 2600 bushels to be the common produce of an acre of ground, then, according to this calculation, they would give 172,800 lbs., containing carbonate of lime 68,160 lbs., gypsum 8509 lbs., oxide of iron 12,987 lbs., saline matter 3538 lbs., charcoal 7780 lbs. In this instance there was undoubtedly a very considerable quantity of matter capable of being active as manure produced in the operation of burning. The charcoal very finely divided, and exposed on a large surface, must be gradually converted into carbonic acid and gypsum and oxide of iron seem to produce the very best effects when applied to lands containing an excess of carbonate of lime. The second specimen was from a soil near Coleorton, in Leicestershire, containing only 4 per cent of carbonate of lime and consisting of three fourths light silicious sand, and about one fourth clay. This had been turf before burning, and 100 parts of the ashes gave 6 parts charcoal, 3 muriate of soda and sulphate of potash, with a trace of vegetable alkali, 9 oxide of iron, and the remainder the earth. In this instance, as in the other, finely divided charcoal was found, the solubility of which would be increased by the presence of the alkali. The third instance was that of a stiff clay, from Mount's Key, Cornwall. This land had been brought into cultivation from a heath, by burning, about ten years before but having been neglected, furze was springing up in different parts of it, which gave rise to the second paring and burning. 100 parts of the ashes contained 8 parts of charcoal, 2 of saline matter, principally common salt, with a little vegetable alkali, 7 oxide of iron, 2 carbonate of lime, the remainder alumina and silica. Here the quantity of charcoal was greater than in the other instances. The salt was probably owing to the vicinity of the sea, it being but two miles off. In this land there was certainly an excess of dead vegetable fibre, as well as unprofitable living vegetable matter.

§196. *Causes of the effects of burning soil.* Many obscure causes have been referred to for the purpose of explaining the effects of paring and burning; but they may be referred entirely to the diminution of the coherence and tenacity of clays, and to the destruction of inert and useless vegetable matter and its conversion into a manure. Dr Darwin, in his *Phytologia*, has supposed that clay, during torrefaction, may absorb some nutritive principles from the atmosphere which afterwards may be supplied to plants but the earths are pure metallic oxides, saturated with oxygen and the tendency of burning is to expel any other volatile principles which they may contain in combination. If the oxide of iron in soils is not saturated with oxygen, torrefaction tends to produce its further union with this principle and hence, in burning, the colour of clay changes to red. The oxide of iron, containing its full proportion of oxygen, has less attraction for acids than any other oxide and is consequently less likely to be dissolved by any fluid acids in the soil and it appears in this state to act in the same manner as the earths. A very ingenious author Neismith (*Elements of Agr.*), supposes that the oxide of iron, when combined with carbonic acid, is poisonous to plants; and that one use of torrefaction is to expel the carbonic acid from it but the carbonate of iron is not soluble in water and is a very inert substance and a luxuriant crop of cresses has been raised in a soil composed of one fifth carbonate of iron, and four fifths carbonate of lime. Carbonate of iron abounds in some of the most fertile soils in England, particularly the red hep soil; and there is no theoretical ground for supposing that carbonic acid, which is an essential food of plants, should, in any of its combinations, be poisonous to them, and it is known that lime and magnesia are both noxious to vegetation, unless combined with this principle.

§197. *The soils improved by burning* are all such as contain too much dead vegetable fibre, and which consequently lose from one third to one half their weight by incineration; and all such as contain their earthy constituents in an impalpable state of division, i. e. the stiff clays and marls, are improved by burning; but in coarse sands, or rich soils containing a just mixture of the earths, and in all cases in which the texture is sufficiently loose, or the organizable matter sufficiently soluble, the process of torrefaction cannot be useful.

§198. *All poor silicious sands are injured by burning.* Young, in his *Essay on Manures*, states "that he found burning injure sand, and the operation is never performed by good cultivators upon silicious sandy soils, after they have once been brought into cultivation."

#### SECTORS. 5. Changing the Condition of Lands in respect to Water

§199. *The water of the soil where superabundant may be withdrawn, and when deficient supplied; these operations with water are independent of its supply as a manure, or as affording the stimulus of heat or cold.*

§200. *Superfluous water may be considered as injurious to all the useful classes of plants,*

by obstructing perspiration and imbibition, and thus dissolving their roots and submerged parts. Where the surface-soil is properly constituted, and rests on a subsoil moderately porous, both will hold water by capillary attraction, and what is not so retained will sink into the interior strata by its gravity; but where the subsoil is retentive, it will resist, or not admit with sufficient rapidity, the percolation of water to the strata below, which accumulating in the surface-soil till its proportion becomes excessive as a component part, not only carries off the extractive matter but diseases the plants. Hence the origin of surface-draining, that is, laying land in ridges or beds, or intersecting it with small open gutters.

2901 *Springs.* Where the upper stratum is porous in some places, and retentive in others, and on a retentive base, the water, in its progress along the porous bed or layer, will be interrupted by the retentive places in a great variety of ways, and there accumulating will burst through the upper surface in the form of springs, which are more injurious than surface-water, as being colder, and generally permanent in their operation. Hence the origin of under-draining in all its varieties of collecting, extracting and conveying water.

2902. The water of rivers may become injurious to lands on their banks, by too frequently overflowing their surface. In this case the stream may be included by mounds of earth or other materials impervious to water and thus aquatic soils rendered dry and fit for useful herbage and aration. The same may be said of lands occasionally overflowed by the sea. Hence the origin of embanking, an art carried to a great extent in Holland and Italy (See *Smecton's Posthumous Works* *Sigismundi, Agr. Tusc.*; *Raccolta dei Autori che trattano dell' Acque*; and our article *Embankment* in *Supp. Encyc. Brit.* 1819.)

2903. *Irrigation.* Plants cannot live without water, any more than they can prosper in soils where it is superabundant and it is therefore supplied by art on a large scale, either by surface or subterraneous irrigation. In both practices the important points are to imitate nature in producing motion, and in applying the water in the mornings or evenings, or under a clouded sky, and also at moderate intervals. The effects of water constantly employed would, in most cases, be such as attend stagnated water aquatic soils, or land-springs and employed in hot sunshine, or after violent heats, it may check evaporation and destroy life, exactly as it happens to those who may have bathed in cold spring water after long and violent exercise in a hot day (*Phytologia*, xv. 3 5)

2904. In surface irrigation the water is conveyed in a system of open channels, which require to be most numerous in such grounds as are under drilled annual crops, and least so in such as are sown in breadths, beds, or ridges, under perennial crops. This mode of watering has existed from time immemorial. The children of Israel are represented as sowing their seed and "watering it with their foot" that is, as Calmet explains it, raising the water from the Nile by a machine worked by the feet, from which it was conducted in such channels as we have been describing. It is general in the south of France and Italy but less required in Britain.

2905. The *Persian wheel*, or *Noria*, an oriental invention of great power and of the most remote antiquity was introduced into Spain by the Moors, and is yet extensively used in the southern and eastern provinces of that kingdom. It consists of a series of earthen jars attached to an endless rope passing over a vertical drum put into motion by a trundle and cog horizontal wheel, which last is usually turned by one bullock or more.

2906. *Subterraneous irrigation* may be effected by a system of drains or covered gutters in the subsoil, which proceeding from a main conduit or other supply can be charged with water at pleasure. For grounds under the culture of annual plants, this mode would be more convenient, and for all others more economical, as to the use of water, than surface irrigation. Where the under-stratum is gravelly, and rests on a retentive stratum, this mode of watering may take place without drains, as it may also on perfectly flat lands, by filling to the brim, and keeping full for several days, surrounding trenches; but the beds or fields between the trenches must not be of great extent. This practice is used in Lombardy on the alluvial lands near the embouchures of the Po. In Lincolnshire the same mode is practised by shutting up the flood gates of the mouths of the great drains in the dry seasons, and thus damming up the water through all the ramifications of the drainage from the sea to their source. This was first suggested by G. Rennie and Sir Joseph Banks, after the drainage round Boston, completed about 1810. A similar plan, on a smaller scale, had been practised in Scotland, where deep moors had been drained and cultivated on the surface, but where, in summer vegetation failed from deficiency of moisture. It was first adopted by J. Smith (See *Essay on the Improvement of Peat-mosses*, 1795) on a farm in Ayrshire, and has subsequently been brought into notice by J. Johnston, the first delineator and professor of Elkington's system of draining.

2907. *Flooding and warping* are modes of irrigation, the former for manuring grass lands, and the latter for enriching the surface of arable lands; while both at the same time gradually raise up the surface of the soil. Irrigation with a view to conveying

additions to the soil has long been practised, and is an evident imitation of the overflowing of elevated lands, whether in meadow or aration. In the former case it is called *irrigation* or *flooding*, and in the latter *warping*. *Warping* is used chiefly as a mode of enriching the soil by an increase of the alluvial depositions, or warp of rivers, during winter, where the surface is not under crop, and is common on the banks of the Ouse.

§208. The *British* process called *colmata* (*faïence*) is nothing more than a variety of the British process called *warping*. In the Val di Chiavari in Tuscany fields which are too low are raised and fertilised by the process called *colmata*, which is done in the following manner.—The field is surrounded by an embankment to confine the water; the dike of the rivulet is broken down so as to admit the muddy water of the high floods; the Chiavari itself is too powerful a body of water to be used for this purpose. It is only the streams that flow into the Chiavari that are used. This water is allowed to settle and deposit its mud on the field. The water is then let off into the river at the lower end of the field by a discharging course called *colata*, and, in French, *cours d'écoulement*. The water-course which conducts the water from a river either to a full for irrigation, or to a mill, is called *gora*. In this manner a field will be raised five and a half, and sometimes seven and a half feet, in ten years. If the dike is broken down to the bottom, the field will be raised the same height in seven years; but then, in this case, gravel is also carried in along with the mud. In a field of twenty five acres, which had been six years under the process of *colmata*, in which the dike was broken down to within three feet of the bottom, the process was seen to be so far advanced that only another year was requisite for its completion. The floods in this instance had been much charged with soil. The water which comes off cultivated land completes the process sooner than that which comes off hill and woodlands. Almost the whole of the Val di Chiavari has been raised by the process of *colmata*.

§209. A proprietor whose field is not adjacent to a stream may conduct the stream through the intervening lands of another proprietor on paying the damages he occasions. The process of *colmata* is expensive, because the ground is unproductive during the seven or eight years that the process lasts; but this is soon repaid with great profit by the fertility of the newly deposited soil.

§210. By the gravel which the rivers carry and deposit their bed is much raised above the level of the adjoining fields; so that, in order to carry off the rain water from the fields drains are formed which pass in arched conduits under the embanked rivers, and go into larger drains which pass to the lowest part of the plain near Arezzo, and there enter the Chiavari.

§211. The soil in the Val di Chiavari is generally the same to the depth of six feet from the surface, and under that is gravel or sand. After the completion of the process of *colmata*, the expense of which is always repaid with profit, the ground is cultivated for five years on the proprietor's own account, and the produce during these five years repays the expense of the process of *colmata* with profit. The first two years it is sown with Indian corn (*grainetico*) and sometimes hemp, the soil being then too strong for wheat. The next three it is sown with wheat, without any manure. The produce of wheat in this highly fertile state of the soil is twenty from one, whilst in the usual state of the ground the return of wheat is from twelve to fourteen from one. After this the field is let out in the ordinary way to the farmers, the *condottini*. (*Norw. Mag.* vol. xxi.)

\*§212. The rationale of irrigation is thus given by Sir H. Davy.—“In general, in nature, the operation of water is to bring earthy substances into an extreme state of division; but in the artificial watering of meadows, the beneficial effects depend upon many different causes, some chemical, some mechanical. Water is absolutely essential to vegetation, and when land has been covered by water in the winter or in the beginning of spring, the moisture which has penetrated deep into the soil, and even the subsoil, becomes a source of nourishment to the roots of the plants in the summer and prevents these bad effects which often happen in lands in their natural state, from a long continuance of dry weather. When the water used in irrigation has flowed over a calcareous country it is generally found impregnated with carbonate of lime and in this state it tends, in many instances, to ameliorate the soil. Common river water also generally contains a certain portion of organic matter, which is much greater after rains than at other times, or which exists in the largest quantity when the stream rises in a cultivated country. Even in cases where the water used for flooding is pure and free from animal or vegetable substances, it acts by causing a more equable diffusion of nutritive matter existing in the land, and in very cold seasons it preserves the tender roots and leaves of the grass from being affected by frost. Water is of greater specific gravity at 42° Fahrenheit, than at 32°, the freezing point, and hence, in a meadow irrigated in winter the water immediately in contact with the grass is rarely below 40°, a degree of temperature not at all prejudicial to the living organs of plants. In 1804, in the month of March, the temperature in a water meadow near Hungerford was examined by a very delicate thermometer. The temperature of the air at seven in the morning was 39°. The water was frozen above the grass. The temperature of the soil below the water in which the roots of the grass were fixed, was 43°. Water may also operate usefully in warm seasons by moderating temperature and thus retarding the over-rapid progress of vegetation. The consequences of this retardation will be greater magnitude and improved texture of the grosser parts of plants, a more perfect and ample development of their finer parts, and, above all, an increase in the use of their fruits and seeds. We apprehend this to be one of the principal uses of flooding rice-grounds in the East, for it is ascertained that the rice-plant will perfect its seeds in Europe, and even in this country, without any water beyond what is furnished by the weather, and the natural moisture of a well constituted soil. It may also be noticed that one variety of rice grows out the declivities of hills without artificial irrigation, as in St. Domingo and in certain parts of India. In general, those waters which breed the best fish are the best fitted for watering meadows; but most of the benefits of irrigation may be derived from any kind of water. It is, however, a general principle, that waters containing ferruginous impregnation, though possessed of fertilising effects when applied to

a calcareous soil, are injurious on soils which do not effervesce with acids; and that calcareous waters, which are known by the earthy deposit they afford when boiled, are of most use on silicious soils, or other soils containing no remarkable quantity of carbonate of lime."

SUMMARY 6 *Changing the Condition of Lands in respect to Atmospheric Influence.*

2213 *The influence of the weather on soils* may be affected by changing the position of their surface and by sheltering or shading.

2214 *Changing the condition of lands, as to solar influence*, is but a limited means of improvement, but is capable of being turned to some account in gardening. It is effected by altering the position of their surface, so as that surface may be more or less at a right angle to the plane of the sun's rays, according as heat or cold is to be increased or diminished. The influence of the sun's rays upon any plane are demonstrated to be as their number and perpendicularity to that plane, the effects of the atmosphere being excepted. Hence one advantage of ridging lands, provided the ridges run north and south for on such surfaces the rays of the morning sun will take effect sooner on the east side and those of the afternoon will remain longer in operation on the west side whilst at mid-day his elevation will compensate, in some degree, for the obliquity of his rays to both sides of the ridge. In culture, on a small scale, ridges or sloping beds for winter-crops may be made south-east and north-west, with their slope to the south, at an angle of forty degrees, and as steep on the north side as the mass can be got to stand and on the south slope of such ridge, *ceteris paribus* it is evident much earlier crops may be produced than on level ground. The north side, however will be lost during this early cropping but as early crops are soon gathered, the whole can be laid level in time for a main crop. Hence all the advantage of grounds sloping to the south south-east, or south-west, in point of precocity and of those sloping to the north for lateness and diminished evaporation. Another advantage of such surfaces is, that they dry sooner after rains, whether by the operation of natural or artificial drainage or in the case of sloping to the south, by evaporation.

2215 *Shelter*, whether by walls, hedges, strips of plantation or trees scattered over the surface, may be considered, generally, as increasing or preserving heat, and lessening evaporation from the soil. But if the current of air should be of a higher temperature than the earth, screens against wind will prevent the earth from being so soon heated and from the increased evaporation arising from so great a multiplication of vegetable surface by the trees, more cold will be produced after rains, and the atmosphere kept in a more moist state, than in grounds perfectly naked. When the temperature of a current of air is lower than that of the earth, screens will prevent its carrying off so much heat but more especially scattered trees, the tops of which will be chiefly cooled whilst the under surfaces of their lower branches reflect back the rays of heat as they radiate from the surface of the soil. Heat, in its transmission from one body to another follows the same laws as light and, therefore, the temperature of the surface in a forest will in winter be considerably higher than that of a similarly constituted soil exposed to the full influence of the weather. The early flowering of plants, in woods and hedges is a proof of this but as such soils cannot be so easily heated in summer and are cooled like others after the sinking in of rains, or the melting of snows, the effect of the reflection as to the whole year is nearly neutralised, and the average temperature of the year of such soils and situations will probably be found not greater than that of open lands.

2216 *Shading* the ground, whether by umbrageous trees, spreading plants, or covering it with tiles, slates, moss, litter, or other materials, has a tendency to exclude atmospheric heat and retain moisture. Shading dry loose soils, by covering them with litter, slates, or tiles, laid round the roots of plants, is found very beneficial.

SUMMARY 7 *Rotation of Crops.*

"2217 *Growing different crops in succession* is a practice which every cultivator knows to be highly advantageous, though its beneficial influence has not yet been fully accounted for by chemists. The most general theory is, that though all plants will live on the same food, as the chemical constituents of their roots and leaves are nearly the same, yet that many species require particular substances to bring their seeds or fruits to perfection as the analysis of these seeds or fruits often afford substances different from those which constitute the body of the plant. A sort of rotation may be said to take place in nature, for perennial herbaceous plants have a tendency to extend their circumference, and rot and decay at their centre, where others of a different kind spring up and succeed them. This is more especially the case with travelling roots, as in mint, strawberry, creeping crowfoot, &c.

2218 *The rationale of rotation* is thus given by Sir H. Davy: — "It is a great advantage in the convertible system of cultivation, that the whole of the manure is employed and that those parts of it which are not fitted for one crop, remain as nourishment for another. Thus, if the turnip is the first in the order of succession, this crop, matured

with water along, immediately finds sufficient soluble matter for its nourishment; and the heat produced in fermentation assists the germination of the seed and the growth of the plant. If, after turnips, barley with grass-seeds is sown, then the land, having been little exhausted by the turnip crop, affords the soluble parts of the decomposing manure to the grain. The grasses, rye-grass, and clover remain, which derive a small part only of their organised matter from the soil, and probably consume the gypsum in the manure which would be useless to other crops—these plants, likewise, by their large systems of leaves, absorb a considerable quantity of nourishment from the atmosphere, or probably retain the nutritive qualities in the soil, for a covering of alates or any other covering would have nearly the same effect—and when ploughed in at the end of two years, the decay of their roots and leaves affords manure for the wheat crop, and at this period of the course, the woody fibre of the farm-yard manure, which contains the phosphate of lime, and the other difficultly soluble parts, is broken down and as soon as the most exhausting crop is taken, recent manure is again applied. Peas and beans, in all instances, seem well adapted to prepare ground for wheat and in some rich lands they are raised in alternate crops for years together. Peas and beans contain a small quantity of a matter analogous to albumen—but it seems that the azote, which forms a constituent part of this matter, is derived from the atmosphere. The dry bean-leaf when burnt, yields a smell approaching to that of decomposing animal matter and in its decay in the soil, may furnish principles capable of becoming a part of the gluten in wheat. Though the general composition of plants is very analogous, yet the specific difference in the products of many of them prove that they must derive different materials from the soil—and though the vegetables having the smallest system of leaves will proportionably most exhaust the soil of common nutritive matter yet particular vegetables, when their produce is carried off, will require peculiar principles to be supplied to the land in which they grow. Strawberries and potatoes at first produce luxuriantly in virgin mould, recently turned up from pasture—but in a few years they degenerate, and require a fresh soil. Lands, in a course of years, often cease to afford good cultivated grasses they become (as it is popularly said) tired of them—and one of the probable reasons for this is, the exhaustion of the gypsum contained in the soil.—Experience," Mr Mann the editor of the *British Farmer's Magazine*, observes, "has proved that land, whatever may be its quality should not be sown with clover at shorter intervals than five years."

2219. *The power of vegetables to exhaust the soil of the principles necessary to their growth, is remarkably exemplified in certain funguses.* Mushrooms are said never to rise in two successive seasons on the same spot—and the production of the phenomena called fairy rings has been ascribed by Dr Wollaston to the power of the peculiar fungus which forms it, to exhaust the soil of the nutriment necessary for the growth of the species. The consequence is, that the ring annually extends, for no seeds will grow where their parents grew before them, and the interior part of the circle has been exhausted by preceding crops—but where the fungus has died, nourishment is supplied for grass, which usually rises within the circle, coarse, and of a dark green colour.

2220. *A rotation is unnecessary, according to Grisenthwaite;* and, in a strict chemical sense, what he asserts cannot be denied. His theory is a refinement on the common idea of the uses of a rotation stated above, but by giving some details of the constituent parts of certain grains and certain manures, he has presented it in a more clear and striking point of view than has hitherto been done. To apply the theory in every case, the constituent parts of all manures and of all plants (1st, their roots and leaves, and 2dly, their seeds, fruits, or grains) must be known. In respect to manures this is the case, and it may be said to be in a great degree the case as to the most useful agricultural plants—but the same cannot be said of garden productions in general, which are very numerous though no branch of culture can show the advantage of a rotation of crops more than horticulture, in the practice of which it is found that grounds become tired of particular crops, notwithstanding that manures are applied at pleasure. If the precise effects of a rotation were ascertained, and the ingredients peculiarly necessary to every species pointed out, nothing could be more interesting than the results of experimental trials, and whoever shall point out a simple and economical mode by which the potato may be grown successively in the same soil, and produce annually, the effects of climate being excepted, as dry and well flavoured tubers, or nearly so, as they generally produce the first and second years on a new soil, will confer a real benefit on society. That wheat may be grown many years on the same soil by the use of animal manures, or such as contain gluten, Grisenthwaite's theory would justify us in believing—and it ought to be fairly tried by such cultivators as Coke and Curwen. Till this is done in the face of the whole agricultural world, and the produce of every crop, and all the particulars of its culture, accurately reported on annually, the possibility of the thing may be asserted to form the premises, but will not be acted on; and, in fact, even the best agricultural chemists do not consider that we are sufficiently advanced in that branch of the science to draw any conclusion, *a priori*, very much at variance with general opinion.

and experience. It should always be kept in mind, that it is one thing to produce a crop, and a different thing to grow crops with profit.

§221 *The principles of rotations of crops are thus laid down by Yvert and Ch. Pictet (Cours complet d'Agriculture, articles Moutonnement, and Succession de Cultures; and Traité des Moutonnements. Paris, 8vo) —*

*The first principle, or fundamental point, is, that every plant exhausts the soil.*  
*The second, that all plants do not exhaust the soil equally.*  
*The third, that plants of different kinds do not exhaust the soil in the same manner.*  
*The fourth, that all plants do not restore to the soil the same quantity nor the same quality of manure.*

*The fifth, that all plants are not equally favourable to the growth of weeds.*

§222. *The following consequences are drawn from these fundamental principles —*

*First.* However well a soil may be prepared, it cannot long nourish crops of the same kind in succession, without becoming exhausted.

*Second.* Every crop impoverishes a soil more or less, as more or less is restored to the soil by the plant cultivated.

*Third.* Perpendicular-rooting plants, and such as root horizontally ought to succeed each other.

*Fourth.* Plants of the same kind should not return too frequently in a rotation.

*Fifth.* Two plants favourable to the growth of weeds, ought not to succeed each other.

*Sixth.* Such plants as eminently exhaust the soil, as the grasses and oil plants, should only be sown when the land is in good heart.

*Seventh.* In proportion as a soil is found to exhaust itself by successive crops, plants which are least exhausting ought to be cultivated.

§223. *Influence of rotations in destroying insects.* Olivier member of the Institute of France, has described all the insects, chiefly *Triples* and *Mûsces*, which live upon the collar or crown of the roots of the cereal grasses, and he has shown that they multiply themselves without end, when the same soil presents the same crop for several years in succession, or even crops of analogous species. But when a crop intervenes on which these insects cannot live, as beans or turneps after wheat or oats, then the whole race of these insects perish from the field, for want of proper nourishment for their larvæ (*Mém. de la Société Royale et Centrale d'Agr. de Paris*, vol. vii.)

## CHAP. II

### Of Manures

§224. *Every species of matter capable of promoting the growth of vegetables may be considered as manure.* On examining the constituents of vegetables, we shall find that they are composed of oxygen, hydrogen, carbon, and nitrogen, or azote, with a small proportion of saline bodies. It is evident, therefore, that the substances employed as manure should also be composed of these elements for, unless they are, there will be a deficiency in some of the elements in the vegetable itself and it is probable that such deficiency may prevent the formation of those substances within it, for which its peculiar organisation is contrived, and upon which its healthy existence depends. The elementary bodies above enumerated are all contained in animal, and the first three in vegetable, matters. Sometimes, though very seldom, vegetables contain a small quantity of nitrogen. As certain salts are also constantly found to be present in healthy living vegetables, manures or vegetable food may, consequently, be distinguished into animal, vegetable, and saline. Kirwan, Dunderland, Darwin, and Davy, who produced the first chemical treatises on soils were also the first to treat chemically of manures. Of these, the latest in the order of time is Sir H. Davy, from whose highly satisfactory work we shall extract the greater part of this chapter.

#### SECT. I. Of Manures of Animal and Vegetable Origin.

§225. *Decaying animal and vegetable substances constitute by far the most important class of manures, or vegetable food, and may be considered as to the theory of their operation, their specific kinds, and their preservation and application in practice.*

SUMMARY. 1. *The Theory of the Operation of Manures of Animal and Vegetable Origin.*

§226. *The rationale of organic manures is very satisfactorily given by Sir H. Davy, who, after having proved that no solid substances can enter in that state into the plant, explains the manner in which nourishment is derived from vegetable and animal substances.*

§227. *Vegetable and animal substances deposited in the soil, as it is shown by universal experience, are consumed during the process of vegetation and they can only nourish the plant by affording solid matters capable of being dissolved by water, or gaseous substances capable of being absorbed by the fluids in the leaves of vegetables, but such parts of them as are rendered gaseous, and pass into the atmosphere, must produce a compensa-*

study small effect, for gases soon become diffused through the mass of the surrounding air. The great object, therefore, in the application of manure should be to make it as fixed as much soluble matter as possible to the roots of the plant and that in a slow and gradual manner, so that it may be entirely consumed in forming its sap and organised parts.

2228. *Mucilaginous, gelatinous saccharine oils, and extractive fluids, carbonic acid, and water*, are substances that in their unchanged states contain almost all the principles necessary for the life of plants but there are few cases in which they can be applied as manures in their pure form, and vegetable manures, in general, contain a great excess of fibrous and insoluble matter which must undergo chemical change, before it can become the food of plants.

2229. *The nature of the changes on these substances; of the causes which occasion them, and which accelerate or retard them, and of the products they afford*, have been scientifically stated and explained by our great agricultural chemist. If any fresh vegetable matter which contains sugar mucilage, starch, or other of the vegetable compounds soluble in water, be moistened, and exposed to air at a temperature from 55° to 80°, oxygen will soon be absorbed, and carbonic acid formed. Heat will be produced, and elastic fluid, principally carbonic acid, gaseous oxide of carbon, and hydro-carbonate will be evolved a dark-coloured liquid, of a slightly sour or bitter taste, will likewise be formed and if the process be suffered to continue for a time sufficiently long nothing solid will remain, except earthy and saline matter, coloured black by charcoal. The dark-coloured fluid formed in the fermentation always contains acetic acid and when albumen or gluten exists in the vegetable substance, it likewise contains volatile alkali. In proportion as there is more gluten, albumen, or matters soluble in water, in the vegetable substances exposed to fermentation, so in proportion, all other circumstances being equal, will the process be more rapid. Pure woody fibre alone undergoes a change very slowly but its texture is broken down, and it is easily resolved into new elements, when mixed with substances more liable to change, containing more oxygen and hydrogen. Volatile and fixed oils, resins, and wax are more susceptible of change than woody fibre, when exposed to air and water but much less liable than the other vegetable compounds and even the most inflammable substances, by the absorption of oxygen become gradually soluble in water. Animal matters in general are more liable to decompose than vegetable substances oxygen is absorbed and carbonic acid and ammonia formed in the process of their putrefaction. They produce feud, compound, elastic fluids, and likewise aceto: they afford dark-coloured acid and oily fluids, and leave a residuum of salts and earths mixed with carbonaceous matter.

2230. *The principal animal substances which constitute their different parts, or which are found in their blood, their secretions, or their excrements, are gelatine, fibrine, mucus, fatty or oily matter, albumen, urea, uric acid, and other acid, saline, and earthy matters.*

2231. *General treatment of organic manures.* Whenever manures consist principally of matter soluble in water it is evident that their fermentation or putrefaction should be prevented as much as possible and the only cases in which these processes can be useful are when the manure consists principally of vegetable or animal fibre. The circumstances necessary for the putrefaction of animal substances are similar to those required for the fermentation of vegetable substances a temperature above the freezing point, the presence of water and the presence of oxygen, at least in the first stage of the process. To prevent manures from decomposing, they should be preserved dry defended from the contact of air and kept as cool as possible. Salt and alcohol appear to owe their powers of preserving animal and vegetable substances to their attraction for water, by which they prevent its decomposing action, and likewise to their excluding air.

#### SUMMARY 2. *Of the different Species of Manures of Animal and Vegetable Origin.*

2232. *The properties and nature of the manures in common use should be known to every cultivator for as different manures contain different proportions of the elements necessary to vegetation, so they require a different treatment to enable them to produce their full effects in culture.*

2233. *All green succulent plants contain saccharine or mucilaginous matter, with woody fibre, and readily ferment.* They cannot, therefore, if intended for manure, be used too soon after their death. Hence the advantage of digging or ploughing in green crops, whether natural or sown on purpose; they must not, however, be turned in too deep, otherwise, as Mrs. Hibberton has shown (*Philos. Mag.* 1816), fermentation will be prevented by compression and exclusion of air. Green crops should be ploughed in, if it be possible, when in flower, or at the time the flower is beginning to appear for it is at this period that they contain the largest quantity of easily soluble matter, and that their leaves are most active in forming nutritive matter. Green crops, pond-weeds, or the passages of hedges or ditches, require no preparation to fit them for manure, nor does any

kind of fresh vegetable matter. The decomposition slowly proceeds beneath the soil; the soluble matters are gradually dissolved and the slight fermentation which goes on, checked by the want of a free communication of air, tends to render the woody fibre soluble without occasioning the rapid dissipation of elastic matter. When old pastures are broken up and made arable, not only has the soil been enriched by the death and slow decay of the plants which have left soluble matters in the soil but the leaves and roots of the grasses living at the time, and occupying so large a part of the surface, afford saccharine, mucilaginous, and extractive matters, which become immediately the food of the crop, and, from their gradual decomposition, afford a supply for successive years.

2254. *Rape-cake*, which is used with great success as manure, contains a large quantity of mucilage, some albuminous matter and a small quantity of oil. This manure should be used recent, and kept as dry as possible before it is applied. It forms an excellent dressing for turnip crops; and is most economically applied by being thrown into the soil at the same time with the seed.

2255. *Malt-dust* consists chiefly of the infant radicle separated from the grain. Sir H. Davy never made any experiment upon this manure but had great reason to suppose that it must contain saccharine matter and this substance will account for its powerful effects. Like rape-cake, it should be used as dry as possible, and its fermentation prevented.

2256. *Linseed-cake* is too valuable as a food for cattle to be much employed as a manure. The water in which flax and hemp are steeped, for the purpose of obtaining the pure vegetable fibre has considerable fertilising powers. It appears to contain a substance analogous to albumen, and likewise much vegetable extractive matter. It putrefies very readily. By the watering process, a certain degree of fermentation is absolutely necessary to obtain the flax and hemp in a proper state the water to which they have been exposed should therefore be used as a manure as soon as the vegetable fibre is removed from it but as flax is generally watered in deep ponds, and sometimes even in streams, it is but seldom that the water is sufficiently impregnated with extractive matter to be worth applying to agricultural purposes.

2257. *Sea-weeds*, consisting of different species of *Fucus* *Algæ* and *Confervæ* are much used as a manure on the sea-coasts of Britain and Ireland. In the Orkney Islands the *Fucus digitatus* is preferred on account of its greater substance. When driven on shore by the winter storms or the gales of spring, it is collected and laid on the land, into which it is then ploughed. In summer it is burnt, with other *Fucus*, into *kelp*. It is a powerful fertiliser but its benefits do not extend beyond one or at most two seasons. By digesting the common *Fucus*, which is the sea-weed usually most abundant on the coast, in boiling water one eighth of a gelatinous substance will be obtained, with characters similar to mucilage. A quantity distilled gave nearly four fifths of its weight of water but no ammonia the water had an empyreumatic and slightly sour taste the ashes contained sea salt, carbonate of soda, and carbonaceous matter. The gaseous matter afforded was small in quantity, principally carbonic acid and gaseous oxide of carbon, with a little hydro-carbonate. This manure is transient in its effects, and does not last for more than a single crop which is easily accounted for from the large quantity of water or the elements of water which it contains. It decays without producing heat when exposed to the atmosphere, and seems, as it were, to melt down and dissolve away. A large heap has been entirely destroyed in less than two years, nothing remaining but a little black fibrous matter. Some of the firmest part of a *Fucus* was suffered to remain in a close jar containing atmospheric air for a fortnight in this time it had become very much shrivelled the sides of the jar were lined with dew. The air examined was found to have lost oxygen and to contain carbonic acid gas. Sea-weed is sometimes suffered to ferment before it is used but this process seems wholly unnecessary, for there is no fibrous matter rendered soluble in the process, and a part of the manure is lost. The best cultivators use it as fresh as it can be procured and the practical results of this mode of applying it are exactly conformable to the theory of its operation. The carbonic acid formed by its incipient fermentation must be partly dissolved by the water set free in the same process; and thus become capable of absorption by the roots of plants. The effects of the sea-weed, as manure, must principally depend upon this carbonic acid, and upon the soluble mucilage the weed contains. Some *Fucus* which had fermented so as to have lost about half its weight, afforded less than one twelfth of mucilaginous matter; from which it may be fairly concluded that some of this substance is destroyed in fermentation.

2258. *Dry straw* of wheat, oats, barley, beans, and peas, spoiled hay, or any similar kind of dry vegetable matter is, in all cases useful manure. In general such substances are made to ferment before they are employed though Sir Humphrey Davy states "it may be doubted whether the practice should be indiscriminately adopted. From 400 grains of dry barley straw eight grains of matter soluble in water were

straw, which had a brown effluve, and tasted like mucklage. From 400 grains of *straw* were obtained *the* *substance* of a similar substance. There can be no doubt that the *straw* of different crops, *immediately* ploughed into the ground, affords nourishment to plants; but there is an objection to this method of using straw, from the possibility of carrying long straw, and from its rendering the husbandry foul. When straw is made an *element*, it becomes a more manageable manure; but there is likewise, on the whole, a great loss of nutritive matter. More manure is perhaps supplied for a single crop, but the land is less improved than it would be, supposing the whole of the vegetable matter could be finely divided and mixed with the soil. It is usual to carry straw that can be employed for no other purpose to the dunghill, to ferment and decompose, but it is worth experiment, whether it may not be more economically applied when chopped small by a proper machine, and kept dry till it be ploughed-in for the use of a crop. In this case, though it would decompose much more slowly, and produce less effect at first, yet its influence would be much more lasting.

2238. *Mr Humphrey Davy's opinion as to the application of farm-yard manure* is in several points directly at variance with the experience of farmers. There may often be an error in allowing such manure to reach too high a degree of fermentation and putrefaction before it is applied to the soil, but in no case has it ever been found advantageous to apply it before the process of fermentation has actually begun. As to its fermenting after being spread upon the soil and ploughed down, it must be evident, upon a little reflection, either that no sensible fermentation would take place at all, unless the quantity were very large, or that its gases would be speedily exhaled through the loose covering of earth and lost in the atmosphere. Mr Coke of Holkham's practice, which has been so often referred to in support of the use of long or fresh dung, is in fact not different from that of the best turnip-land farmers of Scotland. Mr. Blake has shewed, a native of Roxburghshire, prepares his farm-yard manure for turnips in what are called pits or camps in much the same way, and the dung undergoes much the same degree of fermentation in them as is done with the square or oblong dunghills of the turnip counties of Scotland (C).

2240. *More woody fibre* seems to be the only vegetable matter that requires fermentation to render it nutritive to plants. *Tanners' spent bark* is a substance of this kind. A. Young, in his excellent *Essay on Manure*, states "that spent bark seemed rather to injure than assist vegetation" which he attributes to the astringent matter that it contains. But, in fact, it is freed from all soluble substances, by the operation of water in the tannery, and, if injurious to vegetation, the effect is probably owing to its agency upon water, or to its mechanical effects. It is a substance very absorbent and retentive of moisture, and yet not penetrable by the roots of plants.

2241. *Inert peaty matter* is a substance of the same kind. It remains for years exposed to water and air without undergoing change, and in this state yields little or no nourishment to plants. Woody fibre will not ferment, unless some substances are mixed with it which act the same part as the mucilage, sugar, and extractive or albuminous matters with which it is usually associated in herbs and succulent vegetables. Lord Meadowbank has judiciously recommended a mixture of common farm-yard dung for the purpose of bringing peat into fermentation: any putrescible or fermentable substance will answer the end, and the more a substance heats, and the more readily it ferments, the better will it be fitted for the purpose. Lord Meadowbank states, that one part of dung is sufficient to bring three or four parts of peat into a state in which it is fitted to be applied to land: but, of course, the quantity must vary according to the nature of the dung and of the peat. In cases in which some living vegetables are mixed with the peat, the fermentation will be more readily effected.

2242. *Tanners' spent bark*, shavings of wood, and saw-dust, will probably require as much dung to bring them into fermentation as the worst kind of peat. Woody fibre may be likewise prepared, so as to become a manure, by the action of lime. It is evident, from the analysis of woody fibre by Guy Lussac and Thénard (which shows that it consists principally of the elements of water and carbon, the carbon being in larger quantities than in the other vegetable compounds), that any process which tends to abstract carbonaceous matter from it must bring it nearer in composition to the soluble principles, and this is done in fermentation by the absorption of oxygen and production of carbonic acid; and a similar effect, it will be shown, is produced by lime.

2243. *Wood-saves, imperfectly formed, that is, wood-saves containing much charcoal*, are said to have been used with success as a manure. A part of their effects may be owing to the slow and gradual consumption of the charcoal, which seems capable, under other circumstances than those of actual combustion, of absorbing oxygen, so as to become carbonic acid. In April 1806, some well burnt charcoal was enclosed by Sir H. Davy in a tube, which was half filled with pure water and half with common air, and then hermetically sealed. The tube was opened under pure water, in the spring of 1806, at a time when the atmospheric temperature and pressure were nearly the same as at the commencement of the experiment. Some water rushed in, and, on analysing a little air, which was expelled from the tube by the agency of heat, it was found to contain only seven per cent of oxygen. The water in the tube, when mixed with lime-water, produced a copious precipitate, so that carbonic acid had evidently been formed and dissolved by the water.

2244. *Manures from animal substances*, in general, acquire an abundant propagation in fit them for the soil. The great object of the farmer is to blend them with the existing constituents in a proper state of division, and to prevent their too rapid decomposition.

2245. *The entire parts of the muscles of land animals* are not commonly used as manure, though there are many cases in which such an application might be easily made. Horses, dogs, sheep, deer, and other quadrupeds that have died accidentally or of disease, after their skins are separated, are often suffered to remain exposed to the air or immersed in water till they are destroyed by birds or beasts of prey or entirely decomposed; and, in this case, most of their organized matter is lost for the land in which they lie, and a considerable portion of it employed in giving off noxious gases to the atmosphere. By covering dead animals with five or six times their bulk of soil, mixed with one part of lime, and suffering them to remain for a few months, their decomposition would impregnate the soil with soluble matter so as to render it an excellent manure and by mixing a little fresh quicklime with it at the time of its removal, the disagreeable effluvia would be in a great measure destroyed and it might be applied to crops in the same way as any other manure.

2246. *Fish* forms a powerful manure, in whatever state it is applied but it cannot be ploughed in too fresh, though the quantity should be limited. A Young records an experiment, in which herrings spread over a field, and ploughed in for wheat, produced so rank a crop, that it was entirely laid before harvest. The refuse pulchards in Cornwall are used throughout the county as a manure, with excellent effects. They are usually mixed with sand or soil, and sometimes with sea weed, to prevent them from raising too luxuriant a crop. The effects are perceived for several years. In the fens of Lincolnshire, Cambridgehire, and Norfolk, the little fishes called sticklebacks are caught in the shallow waters in such quantities, that they form a great article of manure in the land bordering on the fens. It is easy to explain the operation of fish as a manure. The skin is principally gelatine, which, from its slight state of cohesion is readily soluble in water, fat or oil is always found in fishes, either under the skin or in some of the viscera and their fibrous matter contains all the essential elements of vegetable substances.

2247. Amongst *oily substances* blubber has been employed as a manure. It is most useful when mixed with clay, sand, or any common soil, so as to expose a large surface to the air, the oxygen of which produces soluble matter from it. Lord Somerville used blubber with great success at his farm in Surrey. It was made into a heap with soil, and retained its powers of fertilizing for several successive years. The carbon and hydrogen abounding in oily substances fully account for their effects and their durability is easily explained from the gradual manner in which they change by the action of air and water.

2248. *Bones* are much used as a manure in various parts of England and especially in Lincolnshire and Yorkshire. They are also used in Scotland wherever they can be got, and a knowledge of their great value is spreading rapidly over the Continent. After being broken and boiled for grease, they are sold to the farmer. The more divided they are, the more powerful are their effects. The expense of grinding them in a mill is amply repaid by the increase of their fertilizing powers, and in the state of powder they are used in the drill husbandry, and delivered with the seed in the same manner as rape-cake. Bone-dust and bone-shavings, the refuse of the tanning manufacture, may be advantageously employed in the same way. The basis of bone is constituted by earthy salts, principally phosphate of lime, with some carbonate of lime and phosphate of magnesia, the easily decomposable substances in bone are fat, gelatine, and cartilage, which seems of the same nature as coagulated albumen. According to the analysis of Fourcroy and Vauquelin, ox-bones are composed of decomposable animal matter 51, phosphate of lime 37 7, carbonate of lime 10, phosphate of magnesia 1 9 total 100. To apply bone manure with effect, it is essential that the soil be dry.

2249. *Horn* is a still more powerful manure than bone, as it contains a larger quantity of decomposable animal matter. From 500 grains of ox horn Hatchett obtained only 1 5 grains of earthy residuum, and not quite half of this was phosphate of lime. The shavings or turnings of horn form an excellent manure, though they are not sufficiently abundant to be in common use. The animal matter in them seems to be of the nature of coagulated albumen, and it is slowly rendered soluble by the action of water. The earthy matter in horn, and still more that in bones, prevents the too rapid decomposition of the animal matter, and renders it very durable in its effects.

2250. *Hair, woollen rags, and feathers*, are all analogous in composition, and principally consist of a substance similar to albumen united to gelatine. This is shown by the ingenious researches of Hatchett. The theory of their operation is similar to that of bone and horn shavings.

2251. *The refuse of the different manufactures of skin and leather* forms very useful manures such as currier's shavings, furrier's clippings, and the offals of the tan-yard

and of nitrogenous matter. The gelatine contained in every kind of skin is in a state that renders it liable to solution or decomposition; and when buried in the soil it lasts for many months, and then constantly affords a supply of nutritive matter to the plants in its neighbourhood.

3252. *Blood* contains certain quantities of all the principles found in other animal substances, and is consequently a very good manure. It has been already stated that it contains fibrine, it likewise contains albumen the red particles in it, which have been supposed by many foreign chemists to be coloured by iron in a particular state of combination with oxygen and acid matter. Brande considers as formed of a peculiar animal substance containing very little iron. The scum taken from the boilers of the sugar-houses, which is used as manure, principally consists of bullocks' blood which has been employed for the purpose of separating the impurities of common brown sugar, by means of the coagulation of its albuminous matter by the heat of the boiler.

3253. *The different species of corals, corallines, and sponges* must be considered as substances of animal origin. From the analysis of Hatchett, it appears that all these substances contain considerable quantities of a matter analogous to coagulated albumen the sponges afford likewise gelatine. According to Mariet Guillois, white coral contains equal parts of animal matter and carbonate of lime red coral 46 5 of animal matter, and 53 5 of carbonate of lime; articulated coralline 51 of animal matter, and 49 of carbonate of lime. These substances are never used as manure in this country, except in cases when they are accidentally mixed with sea-weed but it is probable that the corallines might be advantageously employed, as they are found in considerable quantity on the rocks, and bottoms of the rocky pools on many parts of our coast, where the land gradually declines towards the sea and they might be detached by hoes, and collected without much trouble. On many parts of the Scottish coast, banks of shells have been deposited by the sea, and are applied with great advantage, both as a substitute for lime and in improving the mechanical texture of the clay soils within their reach.

3254. Amongst excrementitious animal substances used as manures, urine is the one upon which the greatest number of chemical experiments have been made, and the nature of which is best understood. The urine of the cow contains, according to the experiments of Brande water 65 phosphate of lime 3, murates of potassa and ammonia 15, sulphate of potassa 6 carbonates, potassa, and ammonia 4 urea 4.

3255. *The urine of the horse*, according to Fourcroy and Vauquelin, contains, of carbonates of lime 11 carbonate of soda 3, benzoate of soda 34, murate of potassa 9, urea 7, water and mucilage 940. In addition to these substances, Brande found in it phosphate of lime. The urine of the sea, the camel the rabbit, and domestic fowls, have been submitted to different experiments, and their constitution has been found similar. In the urine of the rabbit, in addition to most of the ingredients above mentioned, Vauquelin detected gelatine and the same chemist discovered uric acid in the urine of domestic fowls. Human urine contains a greater variety of constituents than any other species examined. Urea, uric acid, and another acid similar to it in nature called rosinic acid, acetic acid, albumen, gelatine, a resinous matter and various salts are found in it. The human urine differs in composition, according to the state of the body, and the nature of the food and drink made use of. In many cases of disease there is a much larger quantity of gelatine and albumen than usual in the urine, and in diabetes it contains sugar. It is probable that the urine of the same animal must likewise differ according to the different nature of the food and drink used; and this will account for discordances in some of the analyses that have been published on the subject. Urine is very liable to change, and to undergo the putrefactive process and that of carnivorous animals more rapidly than that of graminivorous animals. In proportion as there is more gelatine or albumen in urine, so in proportion does it putrefy more quickly. The species of urine which contain most albumen, gelatine, and urea, are the best as manures and all urine contains the essential elements of vegetables in a state of solution. During the putrefaction of urine the greatest part of the soluble animal matter that it contains is destroyed it should consequently be used as fresh as possible but if not mixed with solid matter, it should be diluted with water, as, when pure, it contains too large a quantity of animal matter to form a proper fluid nourishment for absorption by the roots of plants.

3256. *Putrid urine* abounds in ammoniacal salts; and though less active than fresh urine, is a very powerful manure. According to a recent analysis published by Berzelius, 1000 parts of urine are composed of, water 938 urea 30 1; uric acid 1; murate of ammonia, free lactic acid, lactate of ammonia, and animal matter 17 14. The remainder different salts, phosphates, sulphates, and murates.

3257. *Dung of birds.* Amongst excrementitious solid substances used as manures, one of the most powerful is the dung of birds that feed on animal food, particularly the dung of sea-birds. The guano, which is used to a great extent in South America, and which is also common that fertilizes the sterile plains of Peru, is a production of this kind. It exists

abundantly, as we are informed by Humboldt, on the small islands in the South Sea, at Chimeo, Ilo, Iau, and Arica. Fifty vessels are laden with it annually at Chimeo, each of which carries from 1500 to 2000 cubical feet. It is used as a manure only in very small quantities; and particularly for crops of maize. Some experiments were made on specimens of guano in 1805. It appeared as a fine brown powder. It blackened by heat, and gave off strong ammoniacal fumes. Treated with nitric acid, it afforded uric acid. In 1806, Fourcroy and Vauquelin published an elaborate analysis of guano. They state that it contains a fourth part of its weight of uric acid, partly saturated with ammonia, and partly with potash; some phosphoric acid combined with the bases, and likewise with lime, small quantities of sulphate and muriate of potash; a little fatty matter; and some quartzose sand. It is easy to explain its fertilising properties from its composition it might be supposed to be a very powerful manure. It requires water for the solution of its soluble matter, to enable it to produce its full beneficial effect on crops.

\*2258 The dung of sea birds has never been much used as a manure in this country but it is probable that even the soil of the small islands on our coast much frequented by them would fertilise. Some dung of sea-birds, brought from a rock on the coast of Merionethshire, produced a powerful, but transient, effect on grass. The rains in our climate must tend very much to injure this species of manure, where it is exposed to them soon after its deposition but it may probably be found in great perfection in caverns or clefts in rocks haunted by cormorants and gulls. Some recent cormorant dung, when examined, had not at all the appearance of guano it was of a greyish white colour had a very fetid smell, like that of putrid animal matter when acted on by quicklime, it gave abundance of ammonia. Treated with nitric acid, it yielded uric acid.

\*2259 Night soil, it is well known, is a very powerful manure, and very liable to decompose. It differs in composition but always abounds in substances composed of carbon, hydrogen, azote, and oxygen. From the analysis of Berzelius, it appears that a part of it is always soluble in water and in whatever state it is used, whether recent or fermented, it supplies abundance of food to plants. The disagreeable smell of night-soil may be destroyed by mixing it with quicklime and if exposed to the atmosphere in thin layers, strewed over with quicklime in fine weather it speedily dries, is easily pulverised, and in this state may be used in the same manner as rape-cake, and delivered into the furrow with the seed. The Chinese, who have more practical knowledge of the use and application of manures than any other people existing, mix their night-soil with one third of its weight of fat marl make it into cakes, and dry it by exposure to the sun. These cakes, we are informed by the French missionaries, have no disagreeable smell, and form a common article of commerce of the empire. The earth, by its absorbent powers, probably prevents, to a certain extent, the action of moisture upon the dung, and likewise defends it from the effects of air. Decalcified night-soil in a state of powder, forms an article of internal commerce in France, and is known under the name of *poudrette*; in London it is mixed with quicklime, and sold in cakes under the name of decalcified night-soil.

\*2260 Pigeon's dung comes next in order as to fertilising power 100 grains, digested in hot water for some hours, produced 25 grains of soluble matter which afforded abundance of carbonate of ammonia by distillation, and left carbonaceous matter, saline matter principally common salt, and carbonate of lime, as a residuum. Pigeons' dung, when moist, readily ferments, and after fermentation contains less soluble matter than before from 100 parts of fermented pigeons' dung, only eight parts of soluble matter were obtained, which gave proportionably less carbonate of ammonia in distillation than recent pigeons' dung. It is evident that this manure should be applied as new as possible and, when dry it may be employed in the same manner as the other manures capable of being pulverised. The soil in woods, where great flocks of wood-pigeons roost, is often highly impregnated with their dung; and, it cannot be doubted would form a valuable manure. Such soil will often yield ammonia when distilled with lime. In the winter likewise, it usually contains abundance of vegetable matter, the remains of decayed leaves and the dung tends to bring the vegetable matter into a state of solution. Manuring with pigeons' dung was, and still is, in great esteem in Fenn.

\*2261 The dung of domestic fowls approaches very nearly in its nature to pigeons' dung. Uric acid is common to it and the dung of birds of every kind. It gives carbonate of ammonia by distillation, and immediately yields soluble matter to water. It is very liable to ferment. The dung of fowls is employed, in common with that of pigeons, by tanners, to bring on a slight degree of putrefaction in skins that are to be used for making soft leather. For this purpose the dung is diffused through water, in which state it rapidly undergoes putrefaction, and brings on a similar change in the skin. The excrements of dogs are employed by the tanner with similar effects. In all cases the contents of the *gastro*, as the part is called in which soft skins are prepared by dung, must form a very useful manure.

2262. *Rabbit's dung* has never been analysed. It is used with great success as a manure by agriculturists, who find it profitable to keep rabbits in such a manner as to prepare their dung. It is sold as fresh as possible, and is found better the less it has fermented.

2263. *The dung of cattle, oxen, and cows* has been chemically examined by Einhof and Thoms. They found that it contained matter soluble in water and that it gave in fermentation nearly the same products as vegetable substances, absorbing oxygen, and producing carbonic acid gas.

2264. *The recent dung of sheep and of deer* affords, when long boiled in water soluble matters which equal from two to three per cent of their weight. These soluble substances, procured by solution and evaporation when examined, contain a very small quantity of matter analogous to animal mucus and are principally composed of a bitter extract, soluble both in water and in alcohol. They give ammoniacal fumes by distillation, and appear to differ very little in composition. Some blades of grass were watered for several successive days with a solution of these extracts; they evidently became greener in consequence, and grew more vigorously than grass in other respects under the same circumstances. The part of the dung of cattle, sheep and deer, not soluble in water, appears to be more woody fibre and precisely analogous to the residuum of those vegetables that form their food after they have been deprived of all their soluble materials.

2265. *The dung of horses* gives a brown fluid, and this, when evaporated, yields a bitter extract, which affords ammoniacal fumes more copiously than that from the dung of oxen.

2266. *In the treatment of the pure dung of cattle, sheep, and horses*, there seems no reason why it should be made to ferment except in the soil like the other pure dungs; or, if suffered to ferment, it should be only in a very slight degree. The grass, in the neighbourhood of recently voided dung is always coarse and dark green some persons have attributed this to a noxious quality in unfermenting dung but it seems to be rather the result of an excess of food furnished to the plants.

2267. *Street and road dung and the sweepings of houses* may be all regarded as composite manures the constitution of them is necessarily various, as they are derived from a number of different substances. These manures are usually applied without being fermented.

2268. *Soot*, which is principally formed from the combustion of pit coal or coal generally, contains likewise substances derived from animal matters. This is a very powerful manure. It affords ammoniacal salts by distillation, and yields a brown extract to hot water, of a bitter taste. It likewise contains an empyreumatic oil. Its great basis is charcoal in a state in which it is capable of being rendered soluble by the action of oxygen and water. This manure is well fitted to be used in the dry state thrown into the ground with the seed, and requires no preparation.

2269. *Liquid Manure*. — The farmers of German Switzerland gave the name of *gülle*, in French *liqeur* to the liquid manure obtained from their stalls and stables, and collected into underground pits or reservoirs, in which it is allowed to ferment in a mucous or almy state. The manner of collecting it adopted by the agriculturists of Zurich is as follows. — The floor on which the cattle are stalled is formed of boards, with an inclination of four inches from the head to the hinder part of the animal, whose excrements fall into a gutter behind, in the manner usual in English cow houses the depth of this gutter is 18 inches, its width 10 inches. It should be so formed as to be capable of receiving, at pleasure, water to be supplied by a reservoir near it it communicates with five pits by holes, which are opened for the passage of the slime, or closed as occasion requires. The pits or reservoirs of manure are covered over with a floor of boarding, placed a little below that on which the animals stand. This covering is important as facilitating the fermentation. The pits or reservoirs are made in masonry, well cemented, and should be bottomed in clay, well beaten, in order to avoid infiltration. They should be five in order that the liquid may not be disturbed during the fermentation which lasts about four weeks. Their dimensions should be calculated according to the number of animals the stable holds, so that each may be filled in a week. But whether full or not, the pit must be closed at the week's end, in order to maintain the regularity of the system of emptying. The reservoirs are emptied by means of portable pumps. In the evening the keeper of the stables lets a proper quantity of water into the gutter and on returning to the stable in the morning, he carefully mixes with the water the excrement that has fallen into it, breaking up the more compact parts, so as to form of the whole an equal and flowing liquid. On the perfect manner in which this process is performed the quality of the manure mainly depends. The liquid ought neither to be thick, for then the fermentation would be difficult, nor too thin, for in that case it would not contain sufficient nutritive matter. When the mixture is made, it is allowed to run off into the pit beneath, and the stable-keeper again lets water into the trench. During the day, whenever

he comes into the stable, he sweeps whatever excrement may be found under the cattle into the trench, which may be emptied as often as the liquid it contains is found to be of a due thickness. The best proportion of the mixture is three fourths of water to one fourth of excrement, if the cattle be fed on corn. If in a course of fattening, one fifth of excrement to four fifths of water will be sufficient. (*Bull. du Comité d'Agri. de la Soc. des Arts de Paris*) This mode of increasing the manure produced by stalled cattle and cows is in general use in Holland and the Netherlands, and we have seen it practised in France at Trappe and Grignon near Versailles, at Roville near Nancy at Ebersberg, and Schleisheim near Munich, and at Hohenheim and Weil near Stuttgart. We would strongly recommend the practice to the British farmer and not to the farmer only, but to every cottager who keeps a cow or pig; nay, to the cottager who is without these comforts, but who has a garden, in which he could turn the great accession of manure so acquired to due account. Let him sink five tubs or large earthen vessels in the ground, and let the contents of the portable receiver of his water-closet, all the water used for washing in the house, soap-suds, slops, and fermentable offals of every description during a week be carried, and poured into one of these tubs and if not full on the Saturday night, let it be filled up with water of any kind well stirred up, the lid replaced, and the whole left for a week. Begin on the Monday morning with another tub, and when after five weeks the whole five are filled, empty the first at the roots of a growing crop, and refill. Or use two larger tubs, and continue filling one for a month then begin the other and at the end of a month empty the first and so on. (*Gard. Mag.* vol. v. p. 549)

SUMMARY 3. *Of the Fermenting, Preserving and Applying of Manures of Animal and Vegetable Origin.*

\*2270. On the management of organic manures depends much of their value as food to plants. The great mass of manures procured by the cultivator are a mixture of animal and vegetable matters, and the great source of supply is the farm or stable-yard. Here the excrementitious matter of horses, cattle, swine, and poultry is mixed with straw, haulm, chaff and various kinds of litter. To what degree should this be fermented before it is applied to the soil? and how can it best be preserved when not immediately wanted?

2271. *A slight incipient fermentation* is undoubtedly of use in the dunghill for, by means of it, a disposition is brought on in the woody fibre to decay and dissolve, when it is carried to the land, or ploughed into the soil and woody fibre is always in great excess in the refuse of the farm. Too great a degree of fermentation is, however, very prejudicial to the composite manure in the dunghill. It is better that there should be no fermentation at all before the manure is used than that it should be carried too far. The excess of fermentation tends to the destruction and dissipation of the most useful part of the manure, and the ultimate results of this process are like those of combustion. It is a common practice amongst farmers to suffer the farm-yard dung to ferment till the fibrous texture of the vegetable matter is entirely broken down and till the manure becomes perfectly cold, and so soft as to be easily cut by the spade. Independently of the general theoretical views unfavourable to this practice, founded upon the nature and composition of vegetable substances, there are many arguments and facts which show that it is prejudicial to the interests of the farmer.

2272. During the violent fermentation which is necessary for reducing farm-yard manure to the state in which it is called short muck, not only a large quantity of fluid, but likewise of gaseous matter, is lost, so much so, that the dung is reduced one half, or two thirds in weight. The principal elastic matter disengaged is carbonic acid with some ammonia and both these, if retained by the moisture in the soil as has been stated before, are capable of becoming a useful nourishment of plants. In October 1808, Sir H. Davy filled a large retort, capable of containing three pints of water with some hot fermenting manure, consisting principally of the litter and dung of cattle. He adapted a small receiver to the retort, and connected the whole with a mercurial pneumatic apparatus, so as to collect the condensable and elastic fluids which might rise from the dung. The receiver soon became lined with dew, and drops began in a few hours to trickle down the sides of it. Elastic fluid likewise was generated in three days (thirty-five cubical inches had been formed, which, when analysed, were found to contain twenty-one cubical inches of carbonic acid the remainder was hydrocarbonate mixed with some azote, probably no more than existed in the common air in the receiver. The fluid matter collected in the receiver at the same time amounted to nearly half an ounce; it had a saline taste and a disagreeable smell, and contained some acetate and carbonate of ammonia. Finding such products given off from fermenting litter, he introduced the neck of another retort, filled with similar dung, very hot at the time, into the soil amongst the roots of some grass in the border of a garden. In less than a week a very distinct effect was produced on the grass upon the spot exposed to the influence of the

matter disengaged in fermentation, it grows with much more luxuriance than the grass in any other part of the garden. — Besides the dissipation of gaseous matter when fermentation is pushed to the extreme, there is another disadvantage in the loss of heat, which, if excited in the soil, is useful in promoting the germination of the seed, and in assisting the plant in the first stage of its growth, when it is most feeble and most liable to disease; and the fermentation of manure in the soil must be particularly favourable to the wheat crop, in preserving a genial temperature beneath the surface late in autumn and during winter. Again, it is a general principle in chemistry, that, in all cases of decomposition, substances combine much more readily at the moment of their disengagement, than after they have been perfectly formed. Now, in fermentation beneath the soil, the fluid matter produced is applied instantly, even whilst it is warm, to the organs of the plant, and consequently is more likely to be efficient, than that from manure which has gone through the process, and of which all the principles have entered into new combinations.

2273 *Checking fermentation by covering* "There are reasons sufficiently strong," Grisebawite observes, "to discourage the practice of allowing dung heaps to ferment and rot without interruption. It appears that public opinion has slowly adopted the decisions of chemical reasoning and *dung-pies*, as they are called, have been formed with a view to save what was before lost, a stratum of mould, sustaining the heap, being placed to receive the fluid parts, and a covering of mould being applied to prevent the dissipation of the aerial or gaseous products. These purposes and contrivances, unfortunately, like many of the other operations of husbandry were not directed by scientific knowledge. To cover is so commonly believed to confine that there is no wonder that the practical cultivator adopted it in this instance from such a consideration but it is in vain the elasticity of the gases generated is such as no covering whatever could possibly confine. If it were perfectly compact, it could only preserve as much carbonic acid as is equal to the volume or bulk of air within it a quantity too inconsiderable to be regarded, could it even be saved but every particle of it must be disengaged, and lost, when the covering is removed."

2274 *Checking fermentation by watering* is sometimes recommended but this practice is inconsistent with just chemical views. It may cool the dung for a short time but moisture, as before stated, is a principal agent in all processes of decomposition. Dry fibrous matter will never ferment. Water is as necessary as air to the process and to supply it to fermenting dung is to supply an agent which will hasten its decay. In all cases when dung is fermenting there are ample tests by which the rapidity of the process, and consequently the injury done, may be discovered. If a thermometer plunged into the dung, does not rise to above one hundred degrees of Fahrenheit, there is little danger of much aeriform matter flying off. If the temperature is higher the dung should be immediately spread abroad. When a piece of paper moistened in muriatic acid, held over the steams arising from a dunghill, gives dense fumes, it is a certain test that the decomposition is going too far, for this indicates that volatile alkali is disengaged.

2275. *In favour of the application of farm-yard dung in a recent state*, a great variety of arguments may be found in the writings of scientific agriculturists; but the practice of the best farmers, both in Scotland and in the Netherlands and other parts of the Continent, is against the theory.

2276 *Farm-yard manure in Scotland* is never laid on the ground without being more or less prepared. For turnips it is regularly removed from the fold or stable yard before the middle or end of April. It is then laid up in a regular heap on a secluded spot of ground, generally in one corner of the field, not much exposed to wind, or liable to be flooded by water. The height of the heap should seldom be less than from 4 to 6 feet, and its breadth, for the convenience of being turned over when necessary and on other accounts, may be about two thirds of its length, sufficiently broad at least to admit two carts or more to be loaded at a time as may be necessary; and great care should be taken, not to put either horse or cart upon it, which is easily avoided, by backing the cart to the pile, and laying the dung compactly together with a dung fork. It is not unusual to cover the dunghill with a coat of earth or moss, which keeps in the moisture, and prevents the sun and wind from doing injury by evaporating these fluid substances, which arise from a valuable part of the dung. Dung when managed in this manner generally ferments very rapidly; but if it is discovered to be in a backward state, it is turned over about the first of May when the weather becomes warm; and the better it is shaken about and mixed, the sooner will the object in view be accomplished. (*Gen. Agr. Scot. vol. ii.*) For wheat crops sown on fallow in autumn, or for beans, potatoes, or other crops sown or planted in spring the farm or fold yard manure is carried out at different times, during the preceding summer and winter and formed into large dunghills in the fields where they are to be used. These dunghills are turned once or twice and moistened by watering, or covered by earth or moss, so as to accelerate or retard the fermentation according to the period when the manure may be wanted for use. The best of their service for this purpose is that degree of heat which admits of the easy separation of the litery parts when a dung shov is inserted and a skiffel taken up.

2277 The doctrine of the proper application of manures from organised substances, offers an illustration of an important part of the economy of nature, and of the happy order in which it is arranged. The death and decay of animal substances tend to resolve organised forms into chemical constituents, and the pernicious effluvia disengaged in the process seem to point out the propriety of burying them in the soil, where they are fitted to become the food of vegetables. The fermentation and putrefaction of

organised substances in the free atmosphere are noxious processes; beneath the surface of the ground, they are salutary operations. In this case the food of plants is prepared where it can be used; and that which would offend the senses and injure the health, if exposed, is converted by gradual processes into forms of beauty and of usefulness; the fixed gas is rendered a constituent of the aroma of the flower, and what might be poison becomes nourishment to animals and to man.

2276. To preserve dung for any time, the situation in which it is kept is of importance. It should, if possible, be defended from the sun. To preserve it under sheds would be of great use or to make the site of a dunghill on the north side of a wall. The floor on which the dung is heaped should, if possible, be paved with flat stones and there should be a little inclination from each side towards the centre, in which there should be drains connected with a small well, furnished with a pump by which any fluid matter may be collected for the use of the land. It too often happens that a dense mucilaginous and extractive fluid is suffered to drain away from the dunghill, so as to be entirely lost to the farm.

## SECT. II Of Manures of Mineral Origin.

2279. *Earthy and saline manures* are probably of more recent invention, and doubtless of more uncertain use, than those of animal and vegetable origin. The conversion into original forms of matter which has belonged to living structures, is a process that can be easily understood but it is more difficult to follow those operations by which earthy and saline matters are consolidated in the fibre of plants, and by which they are made subservient to their functions. These are capable of being materially elucidated by modern chemistry and shall here be considered as to the theory of their operation and as to their specific kinds.

### SUBJECT 1 Theory of the Operation of Mineral Manures

2280. *Saline and calcareous substances* form the principal fossil manures. Much has been written on lime and common salt, both in the way of speculation and reasoning from facts, which, from want of chemical knowledge, has turned to no useful account, and cultivators till very lately contented themselves with stating that these substances acted as stimuli to the soil, something like condiments to the digestive organs of animals. Even chemists themselves are not yet unanimous in all their opinions but still the result of their enquiries will be found of great benefit to the scientific cultivator.

2281. Various opinions exist as to the rationale of the operation of mineral manures. "Some enquirers," Sir H. Davy observes, "adopting that sublime generalisation of the ancient philosophers, that matter is the same in essence, and that the different substances, considered as elements by chemists, are merely different arrangements of the same indestructible particles, have endeavoured to prove, that all the varieties of the principles found in plants, may be formed from the substances in the atmosphere and that vegetable life is a process in which bodies, that the analytical philosopher is unable to change or to form, are constantly composed and decomposed. But the general results of experiments are very much opposed to the idea of the composition of the earths, by plants, from any of the elements found in the atmosphere, or in water and there are various facts contradictory to the idea. Jacquin states, that the ashes of glass-wort (*Salicóla Sida*), when it grows in inland situations, afford the vegetable alkali when it grows on the sea-shore, where compounds which afford the fossil or marine alkali are more abundant, it yields that substance. Du Hamel found that plants which usually grow on the sea-shore made small progress when planted in soils containing little common salt. The sun-flower when growing in lands containing no nitre, does not afford that substance though when watered by a solution of nitre it yields nitre abundantly. The tables of De Saussure show that the ashes of plants are similar in constitution to the soils in which they have vegetated. De Saussure made plants grow in solutions of different salts and he ascertained that, in all cases, certain portions of the salts were absorbed by the plants, and found unaltered in their organs. Even animals do not appear to possess the power of forming the alkaline and earthy substances. Dr Fordyce found that when canary birds, at the time they were laying eggs, were deprived of access to carbonate of lime, their eggs had soft shells and if there is any process for which nature may be conceived most likely to supply resources of this kind, it is that connected with the reproduction of the species.

2282. It seems a fair conclusion, as the evidence on the subject now stands, that the different earths and saline substances found in the organs of plants, are supplied by the soils in which they grow and in no cases composed by new arrangements of the elements in air or water. What may be our ultimate view of the laws of chemistry, or how far our ideas of elementary principles may be simplified, it is impossible to say. We can only reason from facts. We cannot imitate the powers of composition belonging to vegetable structures; but at least we can understand them and as far as our researches have gone,

It appears that in vegetation compound forms are uniformly produced from simple ones, and the elements in the soil, the atmosphere, and the earth absorbed and made parts of beautiful and diversified structures. The views which have been just developed lead to correct ideas of the operation of those manures which are not necessarily the result of decayed organised bodies, and which are not composed of different proportions of carbon, hydrogen, oxygen, and azote. They must produce their effect, either by becoming a constituent part of the plant, or by acting upon its more essential food, so as to render it more fitted for the purposes of vegetable life.

#### SUMMARY. 2. Of the different Species of Mineral Manures.

2283. *Silicious earths, or alibates and their combinations*, which are found unmixed with the remains of any organised beings, are the only substances which can with propriety be called fossil manures. The only alkaline earths which have been hitherto applied in this way are lime and magnesia though potassa and soda, the two fixed alkalies, are both used to a limited extent in certain of their chemical compounds.

2284. *The most common form in which lime is found on the surface of the earth, is in a state of combination with carbonic acid or fixed air*. If a piece of limestone or chalk be thrown into a fluid acid, there will be an effervescence. This is owing to the escape of the carbonic acid gas. The lime becomes dissolved in the liquor. When limestone is strongly heated, the carbonic acid gas is expelled, and then nothing remains but the pure alkaline earth in this case there is a loss of weight and if the fire has been very high, it approaches to one half the weight of the stone but in common cases, limestones, if well dried before burning, do not lose much more than 35 to 40 per cent, or from seven to eight parts out of twenty.

2285. *When burnt lime is exposed to the atmosphere*, in a certain time it becomes mild, and is the same substance as that precipitated from lime-water it is combined with carbonic acid gas. Quicklime, when first made is caustic and burning to the tongue, renders vegetable blues green, and is soluble in water but when combined with carbonic acid, it loses all these properties, its solubility, and its taste it regains its power of effervescing, and becomes the same chemical substance as chalk or limestone. Very few limestones or chalks consist entirely of lime and carbonic acid. The statuary marbles, or certain of the rhomboidal spars, are almost the only pure species and the different properties of limestones, both as manures and cements, depend upon the nature of the ingredient mixed in the limestone for the true calcareous element, the carbonate of lime, is uniformly the same in nature, properties, and effects, and consists of one proportion of carbonic acid 41 4, and one of lime 55. When a limestone does not copiously effervesce in acids, and is sufficiently hard to scratch glass, it contains silicious, and probably aluminous earth; when it is deep brown or red or strongly coloured of any of the shades of brown or yellow it contains oxide of iron when it is not sufficiently hard to scratch glass, but effervesces slowly, and makes the acid in which it effervesces milky, it contains magnesia, and when it is black, and emits a fetid smell if rubbed, it contains oily or bituminous matter. Before any opinion can be formed of the manner in which the different ingredients in limestones modify their properties, it will be necessary to consider the operation of pure lime as a manure.

2286. *Quicklime, in its pure state, whether in powder or dissolved in water, is injurious to plants*. In several instances grass has been killed by watering it with lime-water. But lime, in its state of combination with carbonic acid is a useful ingredient in soils. Calcareous earth is found in the ashes of the greater number of plants; and exposed to the air, lime cannot long continue caustic for the reasons that were just now assigned, but soon becomes united to carbonic acid. When newly burnt lime is exposed to air, it soon falls into powder in this case it is called slacked lime and the same effect is immediately produced by throwing water upon it, when it heats violently and the water disappears. Slacked lime is merely a combination of lime, with about one third of its weight of water; i. e. fifty-five parts of lime absorb seventeen parts of water and in this case it is composed of a definite proportion of water and is called by chemists *hydrate of lime*, and when hydrate of lime becomes carbonate of lime by long exposure to air, the water is expelled, and the carbonic acid gas takes its place. When lime, whether freshly burnt or slacked, is mixed with any moist fibrous vegetable matter, there is a strong action between the lime and the vegetable matter, and they form a kind of compost together, of which a part is usually soluble in water. By this kind of operation, lime renders matter which was before comparatively inert, nutritive, and as charcoal and oxygen abound in all vegetable matters, it becomes at the same time converted into carbonate of lime.

2287. *Mild lime, powdered limestone, marls, or chalks*, have no action of this kind upon vegetable matter; they prevent the too rapid decomposition of substances already dissolved but they have no tendency to form soluble matters. It is obvious from these circumstances, that the operations of quicklime, and marl, or chalk, depend upon prin-

slight altogether different. Quicklime, in being applied to land, tends to bring any hard vegetable matter that it contains into a state of more rapid decomposition and solution, so as to render it a proper food for plants. Chalk, marl, or carbonate of lime, will only improve the texture of the soil, or its relation to absorption; it acts merely as one of its earthy ingredients. Chalk has been recommended as a substance calculated to correct the sourness of land. It would surely have been a wise practice to have previously ascertained the certainty of the existence of acid, and to have determined its nature, in order that it might be effectually removed. The fact really is, that no soil was ever yet found to contain any notable quantity of uncombined acid. The acetic and carbonic acids are the only two that are likely to be generated by any spontaneous decomposition of animal or vegetable bodies, and neither of these has any fixity when exposed to the air. Chalk having no power of acting on animal and vegetable substances, can be no otherwise serviceable to land than as it alters its texture. Quicklime, when it becomes mild, operates in the same manner as chalk, but in the act of becoming mild, it prepares soluble out of insoluble matter. Bouillon la Grange says that gelatine oxygenised becomes moluble, and vegetable extract we know becomes so from the same cause; now lime has the property of attracting oxygen, and, consequently, of restoring the property of solubility to those substances which have been deprived of it, from a combination with oxygen. Hence the uses of lime on peat lands, and on all soils containing an excess of vegetable insoluble matter (*Gristenhouse*).

2288 *Marl, and even shell sand*, have been known to act chemically on peat bogs, and to produce astonishing benefits. True and genuine peat bogs contain a considerable quantity of an acid which has some affinity to gallic acid, and often yield phosphoric acid to analysis. It appears to be these acids which confer on peat earth its highly antiseptic qualities, and prevent the complete decay of woody fibre in such situations. When either true marl or shell sand is laid as a manure in such soils, a rapid decomposition of the vegetable matter takes place, owing to the calcareous matter uniting with the acid which before impregnated the woody fibre, and such land soon becomes very productive, probably also because the carbonic acid of the marl and shell sand is applied to the growth of living vegetables as it is gradually disengaged by the union of these acids with the lime (*T S T*).

2289 *Effect of lime on wheat crops* When lime is employed upon land where any quantity of animal matter is present, it occasions the evolution of a quantity of ammonia, which may perhaps, be imbibed by the leaves of plants, and afterwards undergo some change so as to form gluten. It is upon this circumstance that the operation of lime in the preparation for wheat crops depends, and its efficacy in fertilizing peat, and in bringing into a state of cultivation all soils abounding in hard roots, dry fibres, or inert vegetable matter.

2290 *General principles for applying lime* The solution of the question whether quicklime ought to be applied to a soil, depends upon the quantity of inert vegetable matter that it contains. The solution of the question, whether marl, mild lime, or powdered limestones ought to be applied, depends upon the quantity of calcareous matter already in the soil. All soils which do not effervesce with acids are improved by mild lime, and ultimately by quicklime, and sands more than clays. When a soil, deficient in calcareous matter contains much soluble vegetable manure, the application of quicklime should always be avoided, as it either tends to decompose the soluble matters by uniting to their carbon and oxygen so as to become mild lime, or it combines with the soluble matters, and forms compounds having less attraction for water than the pure vegetable substance. The case is the same with respect to most animal manures, but the operation of the lime is different in different cases, and depends upon the nature of the animal matter. Lime forms a kind of insoluble soap with oily matters, and then gradually decomposes them by separating from them oxygen and carbon. It combines likewise with the animal acids, and probably assists their decomposition by abstracting carbonaceous matter from them combined with oxygen, and consequently it must render them less nutritive. It tends to diminish, likewise, the nutritive powers of albumen from the same causes, and always destroys, to a certain extent, the efficacy of animal manures, either by combining with certain of their elements, or by giving to them new arrangements. Lime should never be applied with animal manures, unless they are too rich, or for the purpose of preventing noxious effluvia. It is injurious when mixed with any common dung, and tends to render the extractive matter insoluble. According to Chaptal (*Chimie appliquée*, &c. l. 153) lime forms insoluble compounds with almost all animal and vegetable substances that are soft, and thus destroys their fermentative properties. Such compounds, however, exposed to the continued action of the air, after in course of time the lime becomes carbonate, the animal or vegetable matters decompose by degrees, and furnish new products as vegetable nourishment. In this view, lime presents two great advantages for the nutrition of plants, the first, that of disposing certain insoluble bodies to form soluble compounds, the second, that of prolonging the

action and nutritive qualities of substances, beyond the term during which they would be retained if these substances were not made to enter into combination with lime. Thus the nutritive qualities of blood, as it exists in the compound of lime and blood known as *superfluus* serum, are moderated, prolonged, and given out by degrees, blood alone, applied directly to the roots of plants, will destroy them with few or no exceptions.

2291 *Lime promotes fermentation* In those cases in which fermentation is useful to produce nutriment from vegetable substances, lime is always efficacious. Some notes upon *linaria* bark was mixed with one fifth of its weight of quicklime, and suffered to remain in a close vessel for three months; the lime had become coloured, and was effervescent: when water was boiled upon the mixture, it gained a tint of fawn-colour, and by evaporation furnished a fawn-coloured powder, which must have consisted of lime united to vegetable matter, for it burnt when strongly heated, and left a residuum of mild lime.

2292. *Different kinds of limestones have different effects.* The limestones containing alumina and silica are less fitted for the purposes of manure than pure limestones; but the lime formed from them has no noxious quality. Such stones are less efficacious, merely because they furnish a smaller quantity of quicklime. There is very seldom any considerable portion of coaly matter in bituminous limestones, never as much as five parts in 100 but such limestones make very good lime. The carbonaceous matter can do no injury to the land, and may, under certain circumstances, become a food of the plant.

2293. *The subject of the application of the magnesian limestone is one of great interest.* It had been long known to farmers in the neighbourhood of Doncaster that lime made from a certain limestone, when applied to the land, often injured the crops considerably. Tennant, in making a series of experiments upon this peculiar calcareous substance, found that it contained magnesia and on mixing some calcined magnesia with soil in which he sowed different seeds, he found that they either died or vegetated in a very imperfect manner, and the plants were never healthy. With great justice and ingenuity he referred the bad effects of the peculiar limestone to the magnesian earth it contains.

2294. *Magnesian limestone is used with good effect in some cases.* Magnesia has a much weaker attraction for carbonic acid than lime, and will remain in the state of caustic or calcined magnesia for many months, though exposed to the air and, as long as any caustic lime remains, the magnesia cannot be combined with carbonic acid, for lime instantly attracts carbonic acid from magnesia. When a magnesian limestone is burnt, the magnesia is deprived of carbonic acid much sooner than the lime, and, if there is not much vegetable or animal matter in the soil to supply by its decomposition carbonic acid, the magnesia will remain for a long while in the caustic state, in which state it acts as a poison to certain vegetables and that more magnesian lime may be used upon rich soils, seems to be owing to the circumstance, that the decomposition of the manure in them supplies carbonic acid. Magnesia in its mild state i.e. fully combined with carbonic acid, seems to be always a useful constituent of soils. Carbonate of magnesia (procured by boiling the solution of magnesia in supercarbonate of potassa) was thrown upon grass, and upon growing wheat and barley, so as to render the surface white, but the vegetation was not injured in the slightest degree and one of the most fertile parts of Cornwall, the Lizard, is a district in which the soil contains mild magnesian earth. It is obvious, from what has been said, that lime from the magnesian limestone may be applied in large quantities to peats; and that where lands have been injured by the application of too large a quantity of magnesian lime, peat will be a proper and efficient remedy.

2295. *A simple test of magnesia in a limestone is its slight effervescence with acids, and its rendering diluted nitric acid, or aqua fortis, milky.* From the analysis of Tennant, it appears to contain from 20.3 to 22.5 magnesia, 29.5 to 31.7 lime, 47.2 carbonic acid 0.6 clay and oxide of iron. Magnesian limestones are usually of a brown or pale yellow colour. They are found in Somersetshire, Leicestershire, Derbyshire, Shropshire, Durham, and Yorkshire, and in many parts of Ireland, particularly near Belfast. In general, when limestones are not magnesian, their purity will be indicated by their loss of weight in burning; the more they lose, the larger is the quantity of calcareous matter they contain. The magnesian limestones contain more carbonic acid than the common limestones and I have found all of them lose more than half their weight by calcination.

2296 *Gypsum.* Besides being used in the forms of lime and carbonate of lime, calcareous matter is applied for the purposes of agriculture in other combinations. One of these bodies is gypsum or sulphate of lime. This substance consists of sulphuric acid (the same body that exists combined with water in oil of vitrol) and lime; and when dry it is composed of 56 parts of lime and 76 parts of sulphuric acid. Common gypsum or selenite, such as that found at Shotover-Hill, near Oxford, contains, besides sul-

phoric acid and lime, a considerable quantity of water; and its composition may be thus expressed: sulphuric acid one proportion 75, lime one proportion 55; water two proportions 24.

2297 *The nature of gypsum is easily demonstrated* if oil of vitriol be added to quicklime, there is a violent heat produced when the mixture is ignited, water is given off, and gypsum alone is the result, if the acid has been used in sufficient quantity and gypsum mixed with quicklime, if the quantity has been deficient. Gypsum, free from water is sometimes found in nature, when it is called anhydrous selenite; it is distinguished from common gypsum by giving off no water when heated. When gypsum, free from water, or deprived of water by heat, is made into a paste with water it rapidly sets by combining with that fluid. Plaster of Paris is powdered dry gypsum, and its property as a cement, and its use in making casts, depend upon its solidifying a certain quantity of water and making with it a coherent mass. Gypsum is soluble in about 500 times its weight of cold water and is more soluble in hot water so that when water has been boiled in contact with gypsum crystals of this substance are deposited as the water cools. Gypsum is easily distinguished by its properties of affording precipitates to solutions of oxalates and of barytic salts. It has been much used in America, where it was first introduced by Franklin on his return from Paris, where he had been much struck with its effects. He sowed the words, *This has been sown with gypsum*, on a field of lucern, near Washington the effects astonished every passenger, and the use of the manure quickly became general, and signally efficacious. It has been advantageously used in Kent, but in most counties of England it has failed, though tried in various ways, and upon different crops.

2298. *Very discordant notions have been formed as to the mode of operation of gypsum.* It has been supposed by some persons to act by its power of attracting moisture from the air but this agency must be comparatively insignificant. When combined with water it retains that fluid too powerfully to yield it to the roots of the plant, and its adhesive attraction for moisture is inconsiderable the small quantity in which it is used likewise is a circumstance hostile to this idea. It has been erroneously said that gypsum assists the putrefaction of animal substances, and the decomposition of manure.

2299. *The ashes of sainfoin, clover and rye grass, afford considerable quantities of gypsum*, and the substance probably is intimately combined as a necessary part of their woody fibre. If this be allowed, it is easy to explain the reason why it operates in such small quantities for the whole of a clover crop, or sainfoin crop, on an acre, according to estimation, would afford by incineration only three or four bushels of gypsum. The reason why gypsum is not generally efficacious, is probably because most cultivated soils contain it in sufficient quantities for the use of the grasses. In the common course of cultivation, gypsum is furnished in the manure for it is contained in stable dung and in the dung of all cattle fed on grass and it is not taken up in corn crops, or crops of peas and beans, and in very small quantities in turnip crops but where lands are exclusively devoted to pasture and hay, it will be continually consumed. Should these statements be confirmed by future enquiries, a practical inference of some value may be derived from them. It is possible, that lands which have ceased to bear good crops of clover or artificial grasses, may be restored by being manured with gypsum. This substance is found in Oxfordshire, Gloucestershire, Somersetshire, Derbyshire Yorkshire, &c. and requires only pulverisation for its preparation.

2300 *Upon the use of sulphate of iron, or green vitriol, which is a salt produced from pest in Bedfordshire, some very interesting documents have been produced by Dr Pearson and there is little doubt that the pest salt and the vitriolic water acted chiefly by producing gypsum.* The soils on which both are efficacious are calcareous; and sulphate of iron is decomposed by the carbonate of lime in such soils. The sulphate of iron consists of sulphuric acid and oxide of iron, and is an acid and a very soluble salt; when a solution of it is mixed with carbonate of lime, the sulphuric acid quits the oxide of iron to unite to the lime, and the compounds produced are insipid and comparatively insoluble.

2301 *Vitriolic impregnations in soils where there is no calcareous matter are injurious*; but it is probably in consequence of their supplying an excess of ferruginous matter to the sap. Oxide of iron, in small quantities, forms a useful part of soils it is found in the ashes of plants, and probably is hurtful only in its acid combinations. The ashes of all plants do not afford gypsum. In general, when a recent pest-salt emits a strong smell, resembling that of rotten eggs when acted upon by vinegar it will furnish gypsum. There is a curious agency of iron in soils which may here be mentioned. Soils containing iron at a minimum of oxidation decompose carbonic acid the oleaginous parts of manures, by converting the brown oxide, which occurs in every acid, into that with a minimum of oxygen, form a substance capable of aiding the nutrition of plants, by affording them carbon from carbonic acid. (T)

2302. *Phosphate of lime is a combination of phosphoric acid and lime, one proportion*

of each. It is a compound insoluble in pure water, but soluble in water containing any acid matter. It forms the greatest part of calcined bones. It exists in most excrementitious substances, and is found both in the straw and grain of wheat, barley, oats, and rye, and likewise in beans, peas, and tares. It exists in many places in these islands native, but only in very small quantities. Phosphate of lime is generally conveyed to the land in the composition of other manure, and it is probably necessary to corn crops and other white crops.

2903 *Bone-ashes* calcined and ground to powder will probably be found useful on arable lands containing much vegetable matter, and may perhaps enable soft peats to produce wheat; but the powdered bone in its uncalcined state is much to be preferred in all cases when it can be procured.

2904. *The ashine compounds of magnesia* will require very little discussion with regard to their uses as manures. In combination with sulphuric acid, magnesia forms a soluble salt. This substance, it is stated by some enquirers, has been found of use as a manure; but it is not found in nature in sufficient abundance, nor is it capable of being made by art sufficiently cheap to be of useful application in the common course of husbandry.

2905. *Wood-ashes* consist principally of the vegetable alkali united to carbonic acid and as this alkali is found in almost all plants, it is not difficult to conceive that it may form an essential part of their organs. The general tendency of the alkalies is to give solubility to vegetable matters and in this way they may render carbonaceous and other substances capable of being taken up by the tubes in the radical fibres of plants. Vegetable alkali likewise has a strong attraction for water and even in small quantities may tend to give a due degree of moisture to the soil, or to other manures though this operation, from the small quantities used or existing in the soil, can be only of a secondary kind.

2906 *The mineral alkali or soda* is found in the ashes of sea-weed, and may be procured by certain chemical agencies from common salt. Common salt consists of the metal named sodium combined with chlorine and pure soda consists of the same metal united to oxygen. When water is present, which can afford oxygen to the sodium soda may be obtained in several modes from salt. The same reasoning will apply to the operation of the pure mineral alkali, or the carbonated alkali, as to that of the vegetable alkali; and when common salt acts as a manure, it is probably by entering into the composition of the plant in the same manner as gypsum phosphate of lime, and the alkalies. Sir John Pringle has stated, that salt in small quantities assists the decomposition of animal and vegetable matter. This circumstance may render it useful in certain soils. Common salt, likewise, is offensive to insects. In small quantities it is sometimes a useful manure, and it is probable that its efficacy depends upon many combined causes. Some persons have argued against the employment of salt because, when used in large quantities, it either does no good, or renders the ground sterile, but this is a very unfair mode of reasoning. That salt in large quantities rendered land barren was known long before any records of agricultural science existed. We read in the Scriptures, that Abimelech took the city of Shechem "and beat down the city, and sowed it with salt;" that the soil might be for ever unfruitful. Virgil reprobates a salt soil, and Pliny though he recommends giving salt to cattle, yet affirms, that when strewed over land it renders it barren. But these are not arguments against a proper application of it. Refuse salt in Cornwall which, however, likewise contains some of the oil and exuvies of fish, has long been known as an admirable manure; and the Cheshire farmers contend for the benefit of the peculiar produce of their county. It is not unlikely, that the same causes as those which act in modifying the operation of gypsum influence the effects of salt. Most lands in this island, particularly those near the sea, probably contain a sufficient quantity of salt for all the purposes of vegetation; and in such cases the supply of it to the soil will not only be useless, but may be injurious. In great storms the spray of the sea has been carried more than fifty miles from the shore; so that from this source salt must be often supplied to the soil. Salt is found in almost all sandstone rocks, and it must exist in the soil derived from these rocks. It is a constituent likewise of almost every kind of animal and vegetable manure. A variety of curious and often contradictory experiments on this subject will be found in *The Gardener's Magazine*, vols. ii. and iii.

2907 *Other compounds.* Besides these compounds of the alkaline earths and alkalies, many others have been recommended for the purposes of increasing vegetation such are nitre, or the nitrous acid combined with potassa. Sir Kenelm Digby states that he made barley grow very luxuriantly by watering it with a very weak solution of nitre; but he is too speculative a writer to excite confidence in his results. This substance consists of one proportion of azote, six of oxygen, and one of potassium; and it is not unlikely that it may furnish azote to form albumen or gluten in those plants which contain them but the nitrous salts are too valuable for other purposes to be used as manures.

Dr. Home states that sulphate of potassa, which was just now mentioned as found in the ashes of some peats, is a useful measure: but Naismith (*Elements of Agriculture*, p. 78.) questions his results, and quotes experiments hostile to his opinions, and, as he conceives, unfavourable to the efficacy of any species of saline measure. Much of the discordance of the evidence relating to the efficacy of saline substances depends upon the circumstance of their having been used in different proportions, and, in general, in quantities much too large.

2308 *Solutions of saline substances* were used twice a week, in the quantity of two tumces, on spots of grass and corn, sufficiently remote from each other to prevent any interference of results. The substances tried were bi-carbonate, sulphate, acetate, nitrate, and muriate of potassa; sulphate of soda, and sulphate, nitrate, muriate, and carbonate of ammonia. It was found, that, in all cases when the quantity of the salt equalled one thirtieth part of the weight of the water, the effects were injurious but least so in the instance of the carbonate, sulphate, and muriate of ammonia. When the quantities of the salts were one three-hundredth part of the solution, the effects were different. The plants watered with the solutions of the sulphates grew just in the same manner as similar plants watered with rain-water. Those acted on by the solution of nitre acetate and carbonate of potassa, and muriate of ammonia, grew rather better. Those treated with the solution of carbonate of ammonia grew most luxuriantly of all. This last result is what might be expected, for carbonate of ammonia consists of carbon, hydrogen, azote and oxygen. There was, however, another result which was not anticipated: the plants watered with solution of nitrate of ammonia did not grow better than those watered with rain-water. The solution reddened litmus paper, and probably the free acid exerted a prejudicial effect, and interfered with the result.

2309 *Soot* doubtless owes part of its efficacy to the ammoniacal salts it contains. The liquor produced by the distillation of coal contains carbonate and acetate of ammonia, and is said to be a very good manure.

2310 *Soapers waste* has been recommended as a manure, and it has been supposed that its efficacy depended upon the different saline matters it contains but their quantity is very minute indeed, and its principal ingredients are mild lime and quicklime. In the soapers waste, from the best manufactories, there is scarcely a trace of alkali. Lime, moistened with sea-water affords more of this substance, and is said to have been used in some cases with more benefit than common lime.

2311 *The result of Sir H. Davy's discussion as to the extent of the effects of saline substances on vegetation* is, that except the ammoniacal compounds, or the compounds containing nitric, acetic and carbonic acid, none of them can afford by their decomposition any of the common principles of vegetation, viz. carbon, hydrogen, and oxygen. The alkaline sulphates and the earthy muriates are so seldom found in plants, or are found in such minute quantities, that it can never be an object to apply them to the soil. The earthy and alkaline substances seem never to be formed in vegetation and there is every reason to believe that they are never decomposed for, after being absorbed, they are found in the ashes. The metallic bases of them cannot exist in contact with aqueous fluids and these metallic bases, like other metals, have not as yet been resolved into any other forms of matter by artificial processes they combine readily with other elements, but they remain indestructible, and can be traced undiminished in quantity through their diversified combinations.

### CHAP. III.

#### *Of the Agency of Heat, Light, Electricity and Water, in Vegetable Culture.*

2312 The particular agency of heat, light, and water in vegetation and culture, has been so frequently illustrated, that it only remains to give a general idea of their nature, and to offer some remarks on electricity.

#### SECT. I. *Of Heat and Light*

2313. *The heat of the sun is the cause of growth, and its light the cause of maturity* in the vegetable kingdom. This is universally acknowledged animals will live without light or with very little; but no plants whatever can exist for any time without the presence of this element. The agency of electricity in vegetation is less known.

2314. *Two opinions are current respecting the nature of heat.* By some philosophers it is conceived to be a peculiar subtile fluid, of which the particles repel each other, but have a strong attraction for the particles of other matter by others it is considered as a motion or vibration of the particles of matter, which is supposed to differ in velocity in

different cases, and thus to produce the different degrees of temperature. Whatever decision be ultimately made respecting these opinions, it is certain that there is matter moving in the space between us and the heavenly bodies capable of communicating heat; the instance of which are rectilinear—thus the solar rays produce heat in acting on the surface of the earth. The beautiful experiments of Dr Herschel have shown that there are rays transmitted from the sun which do not illuminate, and which yet produce more heat than the visible rays—and Ritter and Dr Wollaston have shown that there are other invisible rays distinguished by their chemical effects.

§315 *Heat is radiated by the sun to the earth, and if suffered to accumulate, Dr Wells observes, would quickly destroy the present constitution of our globe. This evil is prevented by the radiation of heat from the earth to the heavens, during the night, when it receives from them little or no heat in return. But through the wise economy of means, which is witnessed in all the operations of nature, the prevention of this evil is made the source of great positive good for the surface of the earth, having thus become colder than the neighbouring air condenses a part of the watery vapour of the atmosphere into dew the utility of which is too manifest to require elucidation. This fluid appears chiefly where it is most wanted on herbage and low plants, avoiding, in great measure, rocks, bare earth, and considerable masses of water. Its production, too, tends to prevent the injury that might arise from its own cause since the precipitation of water upon the tender parts of plants, must in them lessen the cold which occasions it. The prevention, either wholly or in part, of cold, from radiation, in substances on the ground, by the interposition of any solid body between them and the sky arises in the following manner the lower body radiates its heat upwards, as if no other intervened between it and the sky, but the loss, which it hence suffers, is more or less compensated by what is radiated to it, from the body above, the under surface of which possesses always the same, or very nearly the same temperature as the air. The manner in which clouds prevent, or occasion to be small, the appearance of a cold at night upon the surface of the earth, is by radiating heat to the earth, in return for that which they intercept in its progress from the earth towards the heavens. For although, upon the sky becoming suddenly cloudy during a calm night, a naked thermometer suspended in the air commonly rises 2 or 3 degrees, little of this rise is to be attributed to the heat evolved by the condensation of watery vapour in the atmosphere for the heat so extricated must soon be dissipated, whereas the effect of greatly lessening or preventing altogether the appearance of a superior cold on the earth to that of the air, will be produced by a cloudy sky, during the whole of a long night.*

§316 *Dense clouds, near the earth, reflect back the heat they receive from it by radiation. But ampler dense clouds, if very high, though they equally intercept the communication of the earth with the sky, yet being, from their elevated situation colder than the earth, will radiate to it less heat than they receive from it, and may consequently, admit of bodies on its surface becoming several degrees colder than the air. Islands, and parts of continents close to the sea, being, by their situations, subject to a cloudy sky will from the smaller quantity of heat lost by them through radiation to the heavens, at night, in addition to the reasons commonly assigned, be less cold in winter than countries considerably distant from any ocean. But the chief cause why islands, and the coasts of the ocean, are more temperate than continents and inland situations is, that the temperature of the ocean is little from the surface, and where not cooled by contact with ice, is very uniformly about 54° Fahr in all latitudes. The ocean is the great equaliser of heat. (T)*

§317 *Fogs, like clouds, will arrest heat which is radiated upwards by the earth and if they are very dense, and of considerable perpendicular extent, may remit to it as much as they receive. Fogs do not, in any instance, furnish a real exception to the general rule that whatever exists in the atmosphere, capable of stopping or impeding the passage of radiant heat, will prevent or lessen the appearance at night of a cold on the surface of the earth, greater than that of the neighbouring air. The water deposited upon the earth, during a fog at night, may sometimes be derived from two different sources, one of which is a precipitation of moisture from a considerable part of the atmosphere, in consequence of its general cold the other, a real formation of dew, from the condensation, by means of the superficial cold of the ground, of the moisture of that portion of the air which comes in contact with it. In such a state of things, all bodies will become moist, but those especially which most readily attract dew in clear weather.*

§318. *When bodies become cold by radiation, the degree of effect observed must depend, not only on their radiating power but in part also on the greater or less ease with which they can derive heat, by conduction, from warmer substances in contact with them. Bodies, exposed in a clear night to the sky, must radiate as much heat to it during the prevalence of wind, as they would do if the air were altogether still. But in the former case, little or no cold will be observed upon them above that of the atmosphere, so the frequent application of warm air must quickly return a heat equal, or nearly so to that*

which they had lost by radiation. A slight agitation of the air is sufficient to produce some effect of this kind; though, as has already been said, such an agitation, when the air is very pregnant with moisture, will render greater the quantity of dew. One requisite for a considerable production of this fluid being more increased by it, than another is diminished.

2319. It has been remarked that the *hurried effects of cold occur chiefly in hollow places*. If this be restricted to what happens on the serene and calm nights, two reasons from different sources are to be assigned for it. The first is, that the air being still in such a situation, than in any other, the cold, from radiation, in the bodies contained in it, will be less diminished by renewed applications of warmer air. The second, that from the longer continuance of the same air in contact with the ground, in depressed places than in others, less dew will be deposited, and therefore less heat extricated during its formation.

2320. An observation closely connected with the preceding, namely that *in clear and still nights, frosts are less severe upon the hills, than in the neighbouring plains* has excited more attention, chiefly from its contradicting what is commonly regarded an established fact, that the cold of the atmosphere always increases with the distance from the earth. But on the contrary the fact is certain, that, in very clear and still nights, the air near to the earth is colder than that which is more distant from it to the height of at least 320 feet, this being the greatest to which experiments relate. If then a hill be supposed to rise from a plain to the height of 320 feet, having upon its summit a small flat surface covered with grass and if the atmosphere, during a calm and serene night, be admitted to be  $10^{\circ}$  warmer there than it is near the surface of the low grounds, which is a less difference than what sometimes occurs in such circumstances, it is manifest that, should both the grass upon the hill and that upon the plain acquire a cold of  $10^{\circ}$  by radiation, the former will, notwithstanding, be  $10^{\circ}$  warmer than the latter. Hence also the tops of trees are sometimes found dry when the grass on the ground's surface has been found covered with dew.

2321. *A very slight covering will exclude much cold.* I had often observed Dr Wells, in the pride of half knowledge, smiled at the means frequently employed by gardeners, to protect tender plants from cold, as it appeared to me impossible that a thin mat, or any such flimsy substance could prevent them from attaining the temperature of the atmosphere, by which alone I thought them liable to be injured. But, when I had learned that bodies on the surface of the earth become during a still and serene night, colder than the atmosphere, by radiating their heat to the heavens, I perceived immediately a just reason for the practice, which I had before deemed useless. Being desirous, however, of acquiring some precise information on this subject, I fixed, perpendicularly in the earth of a grass-plot, four small sticks, and over their upper extremities, which, were six inches above the grass, and formed the corners of a square the sides of which were two feet long drew tightly a very thin cambric handkerchief. In this disposition of things, therefore, nothing existed to prevent the free passage of air from the exposed grass, to that which was sheltered, except the four small sticks, and there was no substance to radiate heat downwards to the latter grass except the cambric handkerchief. The temperature of the grass which was thus shielded from the sky was upon many nights afterwards, examined by me, and was always found higher than that of neighbouring grass, which was uncovered, if this was colder than the air. When the difference in temperature between the air several feet above the ground and the unsheltered grass did not exceed  $5^{\circ}$  the sheltered grass was about as warm as the air. If that difference however exceeded  $5^{\circ}$  the air was found to be somewhat warmer than the sheltered grass. Thus, upon one night, when fully exposed grass was  $11^{\circ}$  colder than the air the latter was  $5^{\circ}$  warmer than the sheltered grass and the same difference existed on another night, when the air was  $14^{\circ}$  warmer than the exposed grass. One reason for this difference, no doubt, was that the air which passed from the exposed grass, by which it had been very much cooled to that under the handkerchief had deprived the latter of part of its heat. Another, that the handkerchief, from being made colder than the atmosphere by the radiation of its upper surface to the heavens, would remit somewhat less heat to the grass beneath, than what it received from that substance. But still, as the sheltered grass, notwithstanding these drawbacks, was upon one night, as may be collected from the preceding relation,  $8^{\circ}$ , and upon another  $11^{\circ}$ , warmer than grass fully exposed to the sky a sufficient reason was now obtained for the utility of a very slight shelter to plants, in averting or lessening injury from cold, on a still and serene night.

2322. *The covering has most effect when placed at a little distance above the plants or objects to be sheltered.* A difference in temperature of some magnitude, was always observed on still and serene nights, between bodies sheltered from the sky by substances touching them, and similar bodies, which were sheltered by a substance a little above them. I found, for example, upon one night, that the warmth of grass, sheltered by a

cambric handkerchief raised a few inches in the air, was  $2^{\circ}$  greater than that of a neighbouring piece of grass which was sheltered by a similar handkerchief actually in contact with it. On another night the difference between the temperatures of two portions of grass, shielded in the same manner as the two above mentioned from the influence of the sky, was  $4^{\circ}$ . Possibly, concludes Dr Wells, experience has long ago taught gardeners the superior advantage of defending tender vegetables, from the cold of clear and calm nights, by means of substances not directly touching them, though I do not recollect ever having seen any contrivance for keeping mats, or such like bodies, at a distance from the plants which they were meant to protect.

2523. *Heat produced by walls.* Walls, Dr Wells observes, as far as warmth is concerned, are regarded as useful, during a cold night, to the plants which touch them, or are near to them, only in two ways—first, by the mechanical shelter which they afford against cold winds, and secondly, by giving out the heat which they had acquired during the day. It appearing to me, however, that, on clear and calm nights, those on which plants frequently receive much injury from cold, walls must be beneficial in a third way, namely by preventing, in part, the loss of heat, which the plants would sustain from radiation, if they were fully exposed to the sky the following experiment was made for the purpose of determining the justness of this opinion. A cambric handkerchief having been placed, by means of two upright sticks, perpendicularly to a grass-plot, and at right angles to the course of the air, a thermometer was laid upon the grass close to the lower edge of the handkerchief, on its windward side. The thermometer thus situated was several nights compared with another lying on the same grass-plot, but on a part of it fully exposed to the sky. On two of these nights, the air being clear and calm, the grass close to the handkerchief was found to be  $4^{\circ}$  warmer than the fully exposed grass. On a third, the difference was  $6^{\circ}$ . An analogous fact is mentioned by Gersten, who says that a horizontal surface is more abundantly dewed than one which is perpendicular to the ground.

2524. *Heat from a covering of snow.* The covering of snow the same author observes, which countries in high latitudes enjoy during the winter, has been very commonly thought to be beneficial to vegetable substances on the surface of the earth, as far as their temperature is concerned, solely by protecting them from the cold of the atmosphere. But were this supposition just, the advantage of the covering would be greatly circumscribed, since the upper parts of trees and of tall shrubs are still exposed to the influence of the air. Another reason, however, is furnished for its usefulness, by what has been said above, which is, that it prevents the occurrence of the cold, which bodies on the earth acquire, in addition to that of the atmosphere, by the radiation of their heat to the heavens during still and clear nights. The cause, indeed, of this additional cold does not constantly operate, but its presence, during only a few hours, might effectually destroy plants which now pass unhurt through the winter. Again, as things are, while low vegetable productions are prevented, by their covering of snow, from becoming colder than the atmosphere in consequence of their own radiation, the parts of trees and tall shrubs, which rise above the snow, are little affected by cold from this cause: for their uttermost twigs, now that they are destitute of leaves, are much smaller than the thermometers suspended by me in the air, which in this situation very seldom become more than  $5^{\circ}$  colder than the atmosphere. The larger branches, too, which, if fully exposed to the sky would become colder than the extreme parts, are, in a great degree, sheltered by them; and, in the last place, the trunks are sheltered both by the smaller and larger parts, not to mention that the trunks must derive heat, by conduction through the roots, from the earth kept warm by the snow. In a similar way is partly to be explained the manner in which a layer of earth or straw preserves vegetable matters in our own fields from the injurious effects of cold in winter. (*Essay on Dew*.)

2525. *The nature of light is totally unknown.* the light which proceeds from the sun seems to be composed of three distinct substances. Scheele discovered that a glass mirror held before the fire reflected the rays of light, but not the rays of caloric; but when a metallic mirror was placed in the same situation, both heat and light were reflected. The mirror of glass became hot in a short time, but no change of temperature took place on the metallic mirror. This experiment shows that the glass mirror absorbed the rays of caloric, and reflected those of light; while the metallic mirror, suffering no change of temperature, reflected both. If a glass plate be held before a burning body, the rays of light are not sensibly interrupted, but the rays of caloric are intercepted; for no sensible heat is observed on the opposite side of the glass. But when the glass has reached a proper degree of temperature, the rays of caloric are transmitted with the same facility as those of light; and thus the rays of light and caloric may be separated. But the curious experiments of Dr Herschel have clearly proved that the invisible rays which are emitted by the sun have the greatest heating power. In those experiments, the different coloured rays were thrown on the bulb of a very delicate ther-

monometer, and their heating power was observed. The heating power of the violet, green, and red rays were found to be to each other as the following numbers — Violet, 16·0, Green 51·4; Red, 55·0. The heating power of the most refrangible rays was least, and this power increases as the refrangibility diminishes. The red ray therefore, has the greatest heating power and the violet, which is the most refrangible, the least. The illuminating power it has been already observed, is greatest in the middle of the spectrum, and it diminishes towards both extremities but the heating power which is least at the violet end, increases from that to the red extremity and when the thermometer was placed beyond the limit of the red ray it rose still higher than in the red ray, which has the greatest heating power in the spectrum. The heating power of these invisible rays was greatest at the distance of half an inch beyond the red ray, but it was sensible at the distance of one inch and a half.

2126 *The influence of the different solar rays on vegetation* has not yet been studied but it is certain that the rays exercise an influence independent of the heat they produce. Thus plants kept in darkness, but supplied with heat, air, and moisture, grow for a short time, but they never gain their natural colours, their leaves are white and pale, and their juices watery and peculiarly saccharine according to Knight they merely expend the sap previously generated under the influence of light. (*Notes to Sir H. Davy's Agr. Chem.* p. 402.)

#### SECT. II. Of Electricity

2327 *Electrical changes are constantly taking place* in nature, on the surface of the earth and in the atmosphere but as yet the effects of this power on vegetation have not been correctly estimated. It has been shown by experiments made by means of the voltaic battery that compound bodies in general are capable of being decomposed by electrical powers and it is probable that the various electrical phenomena occurring in our system, must influence both the germination of seeds and the growth of plants. It has been found that corn sprouted much more rapidly in water positively electrified by the voltaic instrument, than in water negatively electrified and experiments made upon the atmosphere show that clouds are usually negative and, as when a cloud is in one state of electricity the surface of the earth beneath is brought into the opposite state, it is probable that in common cases the surface of the earth is positive. A similar experiment is related by Dr Darwin (*Phytologia*, sect. xiii 2, 3.)

2328 *Respecting the nature of electricity* different opinions are entertained amongst scientific men. By some, the phenomena are conceived to depend upon a single subtle fluid in excess in the bodies said to be positively electrified, and in deficiency in the bodies said to be negatively electrified a second class suppose the effects to be produced by two different fluids, called by them the vitreous fluid and the resinous fluid and others regard them as affections or motions of matter or an exhibition of attractive powers similar to those which produce chemical combination and decomposition, but usually excluding their action on masses.

2329 *A profitable application of electricity* Dr Darwin observes, to promote the growth of plants is not yet discovered it is nevertheless probable, that, in dry seasons, the erection of numerous metallic points on the surface of the ground, but a few feet high, might in the night time contribute to precipitate the dew by facilitating the passage of electricity from the air into the earth and that an erection of such points higher in the air by means of wires wrapped round tall rods, like angling rods, or elevated on buildings might frequently precipitate showers from the higher parts of the atmosphere. Such points erected in gardens might promote a quicker vegetation of the plants in their vicinity by supplying them more abundantly with the electric ether (*Phytologia*, xiii 4.) J. Williams (*Climate of Great Britain*, 348), enlarging on this idea, proposes to erect large electrical machines, to be driven by wind over the general face of the country for the purpose of improving the climate, and especially for lessening that superabundant moisture which he contends is yearly increasing from the increased evaporating surface, produced by the vegetation of improved culture, and especially from the increase of pastures, hedges, and ornamental plantations.

#### SECT. III. Of Water.

2330. *Water is a compound of oxygen and hydrogen gas*, though primarily reckoned a simple or elementary substance. "If the metal called potassium be exposed in a glass tube to a small quantity of water it will act upon it with great violence; elastic fluid will be disengaged, which will be found to be hydrogen and the same effects will be produced upon the potassium, as if it had absorbed a small quantity of oxygen and the hydrogen disengaged, and the oxygen added to the potassium, are in weight as 2 to 15 and if two in volume of hydrogen, and one in volume of oxygen, which have the weights of 2 and 15, be introduced into a close vessel, and an electrical spark passed through them, they will inflame and condense into 17 parts of pure water."

2331 *Water is absolutely necessary to the economy of vegetation in its elastic and fluid states; and it is not devoid of use even in its solid form. Snow and ice are bad conductors of heat; and when the ground is covered with snow, or the surface of the soil or of water is frozen, the roots or bulbs of the plants beneath are protected by the congealed water from the influence of the atmosphere, the temperature of which, in northern winters, is usually very much below the freezing point; and this water becomes the first nourishment of the plant in early spring. The expansion of water during its congealation, at which time its volume increases one twelfth, and its contraction of bulk during a thaw, tend to pulverise the soil, to separate its parts from each other, and so make it more permeable to the influence of the air*

#### CHAP. IV

##### *Of the Agency of the Atmosphere in Vegetation.*

2332. *The aerial medium which envelopes the earth may be studied chemically and physically: the first study respects the elements of which the atmosphere is composed and the second their action in a state of combination, and as influenced by various causes, or those phenomena which constitute the weather*

##### SECT. I *Of the Elements of the Atmosphere.*

2333. *Water, carbonic acid gas, oxygen, and azote, are the principal substances composing the atmosphere; but more minute enquiries respecting their nature and agencies are necessary to afford correct views of its uses in vegetation.*

2334. *That water exists in the atmosphere is easily proved. If some of the salt, called muriate of lime, which has been just heated red, be exposed to the air, even in the driest and coldest weather, it will increase in weight, and become moist; and in a certain time will be converted into a fluid. If put into a retort and heated, it will yield pure water will gradually recover its pristine state, and, if heated red, its former weight so that it is evident that the water united to it was derived from the air. That it existed in the air in an invisible and elastic form, is proved by the circumstances, that if a given quantity of air be exposed to this salt, its volume and weight will diminish, provided the experiment be correctly made.*

2335. *The quantity of water which exists in air, as vapour, varies with the temperature. In proportion as the weather is hotter the quantity is greater. At 50° of Fahrenheit, air contains about  $\frac{1}{10}$  of its volume of vapour, and, as the specific gravity of vapour is to that of air nearly as 10 to 15, this is about  $\frac{1}{15}$  of its weight. At 100°, supposing that there is a free communication with water it contains about  $\frac{1}{10}$  part in volume, or  $\frac{1}{15}$  in weight. It is the condensation of vapour, by diminution of the temperature of the atmosphere, which is probably the principal cause of the formation of clouds, and of the deposition of dew, mist, snow, or hail.*

2336. *The power of different substances to absorb aqueous vapour from the atmosphere by cohesive attraction has been already referred to. The leaves of living plants appear to act upon this vapour in its elastic form, and to absorb it. Some vegetables increase in weight from this cause, when suspended in the atmosphere and unconnected with the soil: such are the house-leek, and different species of the aloe. In very intense heats, and when the soil is dry, the life of plants seems to be preserved by the absorbent power of their leaves, and it is a beautiful circumstance in the economy of nature, that aqueous vapour is most abundant in the atmosphere when it is most needed for the purposes of life, and that when other sources of its supply are cut off, this is most copious.*

2337. *The existence of carbonic acid gas in the atmosphere is proved by the following process: if a solution of lime and water be exposed to the air, a pellicle will speedily form upon it, and a solid matter will gradually fall to the bottom of the water, and in a certain time the water will become tasteless, this is owing to the combination of the lime which was dissolved in the water with carbonic acid gas, which existed in the atmosphere, as may be proved by collecting the film and the solid matter, and igniting them strongly in a little tube of platinum or iron, they will give out carbonic acid gas, and will become quicklime, which, added to the same water, will again bring it to the state of lime-water.*

2338. *The quantity of carbonic acid gas in the atmosphere is very small. It is not easy to determine it with precision, and it most differ in different situations; but where there is a free circulation of air, it is probably never more than one 500th, nor less than one 800th, of the volume of air. Carbonic acid gas is nearly one third heavier than the other elastic parts of the atmosphere in their mixed state, hence, at first view, it might be supposed*

that it would be most abundant in the lower regions of the atmosphere but unless it has been immediately produced at the surface of the earth in some chemical process, this does not seem to be the case; elastic fluids of different specific gravities have a tendency to equal mixture by a species of attraction, and the different parts of the atmosphere are constantly agitated and blended together by winds or other causes. De Saussure found lime-water precipitated on Mount Blanc, the highest point of land in Europe and carbonic acid gas has been always found, apparently in due proportion, in the air brought down from great heights in the atmosphere by aeronautic adventurers.

2339 *The principal consumption of the carbonic acid in the atmosphere seems to be in affording nourishment to plants and some of them appear to be supplied with carbon chiefly from this source.*

2340 *The formation of carbonic acid gas takes place during fermentation, combustion putrefaction, respiration, and a number of operations taking place upon the surface of the earth and there is no other extensive operation known in nature, by which it can be destroyed but by vegetation.*

2341 *Oxygen and azote are the remaining constituents of the atmosphere. After a given portion of common air has been deprived of aqueous vapour and carbonic acid gas, it appears little altered in its properties it remains a compound of oxygen and azote which supports combustion and animal life. There are many modes of separating these two gases from each other. A simple one is by burning phosphorus in a confined volume of air this absorbs the oxygen and leaves the azote and 100 parts in volume of air in which phosphorus has been burnt, yield 79 parts of azote and by mixing this azote with 21 parts of fresh oxygen gas artificially procured, a substance having the original characters of air is produced. To procure pure oxygen from air, quicksilver may be kept heated in it, at about 600° till it becomes a red powder this powder, when ignited, will be restored to the state of quicksilver by giving off oxygen.*

2342 *Oxygen is necessary to some functions of vegetables but its great importance in nature is its relation to the economy of animals. It is absolutely necessary to their life. Atmospheric air taken into the lungs of animals, or passed in solution in water through the gills of fishes, loses oxygen, and for the oxygen lost, about an equal volume of carbonic acid appears.*

2343 *The effects of azote in vegetation are not distinctly known. As it is found in some of the products of vegetation, it may be absorbed by certain plants from the atmosphere. It prevents the action of oxygen from being too energetic and serves as a medium in which the more essential parts of the air act nor is this circumstance uncomfortable to the analogy of nature for the elements most abundant on the solid surface of the globe are not those which are the most essential to the existence of the living beings belonging to it.*

2344 *The action of the atmosphere on plants differs at different periods of their growth and varies with the various stages of the development and decay of their organs. If a healthy seed be moistened and exposed to air at a temperature not below 45° it soon germinates and shoots forth a plumbe which rises upwards, and a radicle which descends. If the air be confined it is found that in the process of germination the oxygen, or a part of it, is absorbed. The azote remains unaltered no carbonic acid is taken away from the air on the contrary, some is added. Seeds are incapable of germinating, except when oxygen is present. In the exhausted receiver of the air-pump, in pure azote, or in pure carbonic acid, when moistened they swell, but do not vegetate and if kept in these gases, lose their living powers, and undergo putrefaction. If a seed be examined before germination, it will be found more or less insipid, at least not sweet, but after germination it is always sweet. Its coagulated mucus, or starch, is converted into sugar in the process; a substance difficult of solution is changed into one easily soluble and the sugar carried through the cells or vessels of the cotyledons is the nourishment of the infant plant. The absorption of oxygen by the seed in germination has been compared to its absorption in producing the evolution of fetal life in the egg but this analogy is only remote. All animals, from the most to the least perfect classes, require a supply of oxygen. From the moment the heart begins to pulsate till it ceases to beat, the aeration of the blood is constant, and the function of respiration invariable. Carbonic acid is given off in the process but the chemical change produced in the blood is unknown, nor is there any reason to suppose the formation of any substance similar to sugar. It is evident, that in all cases of semination the seeds should be sown so as to be fully exposed to the influence of the air, and one cause of the unproductiveness of cold clayey adhesive soils is, that the seed is coated with matter impermeable to air. In sandy soils the earth is always sufficiently penetrable by the atmosphere, but in clayey soils there can scarcely be too great a mechanical division of parts. Any seed not fully supplied with air, always produces a weak and diseased plant. We have already seen that carbon is added to plants from the air by the process of vegetation in sunshine and oxygen is added to the atmosphere at the same time. It is worthy of remark that the*

absence of light is necessary in the formation of sugar in the germination of seeds; and as *preparator* to the production of sugar in fruits. The following is the late Dr Murray's ingenious explanation of these remarkable facts. The seed consists chiefly of farinaceous matter, which requires oxygen to convert it into sugar. Now living vegetables appear to absorb oxygen in the dark: unripe fruits usually contain an acid, that is, have an excess of oxygen; and light is favourable to the evolution of oxygen from living plants. (T)

2345. *Three changes in the atmosphere which constitute the most important meteorological phenomena may be classed under five distinct heads: the alterations that occur in the weight of the atmosphere; those that take place in its temperature; the changes produced in its quantity by evaporation and rain; the excessive agitation to which it is frequently subject; and the phenomena arising from electric and other causes, which at particular times occasion or attend the precipitations and agitations alluded to. All the above phenomena prove to demonstration that constant changes take place, the consequences of new combinations and decompositions rapidly following each other.*

2346. With respect to the changes in the weight of the atmosphere, it is generally known that the instrument called the barometer shows the weight of a body of air immediately above it, extending to the extreme boundary of the atmosphere and the base of which is equal to that of the mercury contained within it. As the level of the sea is the lowest point of observation, the column of air over a barometer placed at that level is the longest that can be obtained.

2347. *The variations of the barometer between the tropics are very trifling, they increase gradually as the latitude advances towards the poles, till in the end it amounts to two or three inches. The following Table will explain this gradual increase:—*

Latitude.	Place.	Range of the Barometer.	
		Greatest.	Least.
0° 0'	Panama	29.50	—
22 32	Colombia	0.77	—
33 33	Cape Town	—	0.83
40 45	Nagasaki	1.00	—
51 1	Dover	2.07	1.90
55 15	Middleburgh	2.00	1.94
55 23	Liverpool	2.86	1.94
59 28	Peterborough	2.45	2.77

2348. *The range of the barometer is considerably less in North America than in the corresponding latitudes of Europe, particularly in Virginia, where it never exceeds 1.1. The range is more considerable at the level of the sea than on mountains; and in the same degree of latitude it is in the inverse ratio of the height of the place above the level of the sea. Cotte composed a table, which has been published in the Journal de Physique from which it appears extremely probable that the barometer has an invariable tendency to rise between the morning and the evening, and that this impulse is most considerable from two in the afternoon till nine at night, when the greatest elevation is accomplished; but the*

observation at nine differs from that at two by four twelfths, while that of two varies from the elevation of the morning only by one twelfth, and that in particular climates the greatest elevation is at two o'clock. The observations of Cotte confirm those of Luke Howard; and from them it is concluded, that the barometer is influenced by some depressing cause at new and full moon, and that some other makes it rise at the quarters. This coincidence is most considerable in fair and calm weather: the depression in the interval between the quarters and conjunctions amounts to one tenth of an inch, and the rise from the conjunctions to the quarters is to the same amount. The range of this instrument is found to be greater in winter than in summer: for instance, the mean at York, during the months from October to March inclusive, in the year 1776, was 1.44, and in the six summer months 1.06.

2349. *The more serene and settled the weather the higher the barometer ranges: calm weather, with a tendency to rain, depresses it; high winds have a similar effect on it; and the greatest elevation occurs with easterly and northerly winds; but the south produces a directly contrary effect.*

2350. *The variations in the temperature of the air in any particular place, exclusive of the differences of seasons and climates, are very considerable. These changes cannot be produced by heat derived from the sun, as its rays concentrated have no kind of effect on air; these, however, heat the surface of our globe, from which heat is communicated to the immediate atmosphere; it is through this fact that the temperature is highest where the place is so situated as to receive with most effect the rays of the sun, and that it varies in each region with the season; it is also the cause why it decreases in proportion to the height of the air above the surface of the earth. The most perpendicular rays falling on the globe at the equator, there its heat is the greatest, and that heat decreases gradually to the poles, of course the temperature of the air is in exact union, from this it appears that the air acquires the greatest degree of warmth at the equator, whence it becomes insensibly cooler till we arrive at the poles, in the same manner the air immediately above the equator cools gradually. Though the temperature sinks as it approaches the pole, and is highest at the equator, yet as it varies continually with the seasons, it is impossible to form an accurate idea of the progression without forming a mean temperature for a year, from that of the temperature of every degree of latitude for every day of the year, which may be accomplished by adding together the whole of the observations and dividing by their number, when the quotient will be the mean temperature for the year. The "diminution," says Dr Thomson, "from the pole to the equator takes place in arithmetical progression; or to speak more properly, the annual temperature of all the latitudes are arithmetical means between the mean annual temperature of the equator and the pole; and, as far as heat depends on the action of solar rays, that of each month is as the mean altitude of the sun, or rather as the sine of the sun's altitude. Later observations, however, have shown that all the formulae for calculating the mean temperatures of different latitudes, which are founded on Mayer's*

*Empirical Equation*, though tolerably accurate in the Northern Atlantic Ocean, to latitude  $40^{\circ}$ , are totally irreconcilable with observations in very high latitudes and on the meridians, from  $70^{\circ}$  to  $90^{\circ}$  W and E. of London. The results of late arctic voyages, and of Russian travels, have been satisfactorily shown, by Dr Brewster (*Edin Phil. Tr.*), to prove the existence of two meridians of greatest cold in the northern hemisphere and the mean temperature of particular countries varies, not only according to the parallels of latitude, but also according to their proximity to these two cold meridians. (*T*)

2351 *Incomparable seas*, in temperate and cold climates, are colder in winter and warmer in summer than the main ocean, as they are necessarily under the influence of natural operations from the land. Thus the Gulf of Bothnia is generally frozen in winter, but the water is sometimes heated in the summer to  $70^{\circ}$ , a state which the opposite part of the Atlantic never acquires the German Sea is five degrees warmer in summer than the Atlantic, and more than three colder in winter the Mediterranean is almost throughout warmer both in winter and summer which therefore causes the Atlantic to flow into it, and the Black Sea, being colder than the Mediterranean, flows into the latter

2352 *The eastern parts of North America*, as it appears from meteorological tables, have a much colder air than the opposite European coast, and fall short of the standard by about ten or twelve degrees. There are several causes which produce this considerable difference. The greatest elevation in North America is between the  $40^{\text{th}}$  and  $60^{\text{th}}$  degree of north latitude, and the  $100^{\text{th}}$  and  $110^{\text{th}}$  of longitude west from London; and there the most considerable rivers have their origin. The height alone will partly explain why this tract is colder than it would otherwise be but there are other causes, and these are most extensive forests, and large swamps and morasses, all of which exclude heat from the earth and consequently prevent it from ameliorating the rigour of winter. Many extensive lakes lie to the east, and Hudson's Bay more to the north a chain of mountains extends on the south of the latter and those equally prevent the accumulation of heat; besides, this bay is bounded on the east by the mountainous country of Labrador and has many islands from all which circumstances arise the lowness of the temperature, and the piercing cold of the north-west winds. The annual decrease of the forests for the purpose of clearing the ground, and the consumption for building and fuel is supposed to have occasioned a considerable decrease of cold in the winter and if this should be the result, much will yet be done towards bringing the temperature of the European and American continents to something like a level.

2353 *Continents* have a colder atmosphere than islands situated in the same degree of latitude and countries lying to the windward of the superior classes of mountains, or forests, are warmer than those which are to the leeward. Earth always possessing a certain degree of moisture, has a greater capacity to receive and retain heat than sand or stones, the latter therefore are heated and cooled with more rapidity it is from this circumstance that the intense heats of Africa and Arabia, and the cold of Terra del Fuego, are derived. The temperature of growing vegetables changes very gradually but there is a considerable evaporation from them if those exist in great numbers and congregated, or in forests, their foliage preventing the rays of the sun from reaching the earth, it is perfectly natural that the immediate atmosphere must be greatly affected by the ascent of chilled vapours.

2354 Our next object is the ascent and descent of water the principal appearances of this element are vapour, clouds, dew rain frost, hail snow, and ice.

2355 *Vapour* is water rarefied by heat, in consequence of which, becoming lighter than the atmosphere, it is raised considerably above the surface of the earth, and afterwards by a partial condensation forms clouds. It differs from exhalation, which is properly a dispersion of dry particles from a body. When water is heated to  $212^{\circ}$  it boils and is rapidly converted into steam and the same change takes place in much lower temperatures, but in that case the evaporation is slower and the elasticity of the steam is smaller. As a very considerable proportion of the earth's surface is covered with water and as this water is constantly evaporating and mixing with the atmosphere in the state of vapour, a precise determination of the rate of evaporation must be of very great importance in meteorology. Evaporation is confined entirely to the surface of the water hence it is, in all cases, proportional to the surface of the water exposed to the atmosphere. Much more vapour of course rises in maritime countries or those interspersed with lakes, than in inland countries. Much more vapour rises during hot weather than during cold hence the quantity evaporated depends in some measure upon temperature. The quantity of vapour which rises from water even when the temperature is the same varies according to circumstances. It is least of all in calm weather greater when a breeze blows, and greatest of all with a strong wind. From experiments, it appears, that the quantity of vapour raised annually at Manchester is equal to about 25 inches of rain. If to this we add five inches for the dew, with Dalton, it will make the annual evaporation 30 inches. Now if we consider the situation of England, and the greater quantity of vapour raised from water it will not surely be considered as too great an allowance, if we estimate the mean annual evaporation over the whole surface of the globe at 35 inches.

2356. *A cloud* is a mass of vapour more or less opaque, formed and sustained at considerable height in the atmosphere probably by the joint agencies of heat and

electricity. The first successful attempt to arrange the diversified forms of clouds, under a few general modifications, was made by Luke Howard, Esq. We shall give here a brief account of his ingenious classification.

2357 The simple modifications are thus named and defined — 1. Cirrus, parallel, squamæ, or diverging fibres, extensible in any or in all directions (fig. 307 a.);

307

2. Cumulus, convex or conical heaps, increasing upwards from a horizontal base (b);

3. Stratus, a widely-extended, continuous, horizontal sheet, increasing from below (c).

2358 The intermediate modifications which require to be noticed are, 4. Cirro-cumulus, small, well defined, rounded masses, in close horizontal arrangement (d). 5. Cirro-stratus, horizontal, or slightly inclined masses, attenuated towards a part or the whole of their circumference, bent downward or undulated, separate, or in groups consisting of small clouds having these characters e).

2359. The compound modifications are, 6. Cumulo-stratus, or twin cloud, the cirro-stratus blended with the cumulus, and either appearing intermixed with the heaps of the latter, or superadding a wide-spread structure to its base (f); 7. Cumulo-cirro-stratus, or Nimbus, the rain-cloud, a cloud or system of clouds from which rain is falling. It is a horizontal sheet, above which the cirrus spreads, while the cumulus enters it laterally and from beneath (g, g'). 8. The Fall Cloud, resting apparently on the surface of the ground (A).

2353. The *cirrus* appears to have the least density, the greatest elevation, the greatest variety of extent and direction, and to appear earliest in stormy weather, being indicated by a few threads parallel on the sky. Before storms they appear lower and denser, and usually in the quarter opposite to that from which the storm arises. Steady high winds are also preceded and attended by cirrus streaks, running quite across the sky in the direction they blow in.

2354. The *cumulus* has the densest structure, is formed in the lower atmosphere, and moves along with the current next the earth. A small irregular spot first appears, and is, as it were, the nucleus on which they increase. The lower surface continues irregularly plane, while the upper rises into conical or hemispherical humps, which may afterwards continue long nearly of the same bulk, or rapidly rise into mountains. They will begin in fair weather to form some hours after sunrise, arrive at their maximum in the hottest part of the afternoon, then go on diminishing and totally disperse about sunset. Previously to rain the cumulus increases rapidly appears lower in the atmosphere, and with its surface full of loose flosses or protuberances. The formation of large cumuli to leeward in a strong wind, indicates the approach of a calm with rain. When they do not disappear or subside about sunset, but continue to rise, thunder is to be expected in the night.

2355. The *stratus* has a mean degree of density and is the lowest of clouds, its inferior strata commonly resting on the earth in water. This is properly the cloud of night, appearing about sunset. It comprehends all those evening mists which in calm weather ascend in spreading sheets (like an inundation of water) from the bottoms of valleys, and the surfaces of lakes and rivers. On the return of the sun the level surface of the cloud begins to put on the appearance of cumulus, the whole at the same time separating from the ground. The continuity is next destroyed, and the cloud ascends and evaporates, or passes off with the appearance of the nascent cumulus. This has long been experienced as a prognostic of fair weather.

2356. *Transition of forms.* The cirrus having continued for some time increasing or stationary usually passes either to the cirro-cumulus or the cirro-stratus, at the same time descending to a lower station in the atmosphere. This modification forms a very beautiful sky and is frequently in summer an attendant on warm and dry weather. The cirro-stratus, when seen in the distance, frequently gives the idea of shoals of fish. It precedes wind and rain, is seen in the intervals of storms and sometimes alternates with the cirro-cumulus in the same cloud, when the different evolutions form a curious spectacle. A judgment may be formed of the weather likely to ensue by observing which modification prevails at last. The solar and lunar haloes, as well as the parhelia and paraseleae (mock sun and mock moon) prognostics of foul weather, are occasioned by this cloud. The cumulo-stratus precedes, and the nimbus accompanys rain.

2357. *Dew* is the moisture insensibly deposited from the atmosphere on the surface of the earth. This moisture is precipitated by the cold of the body on which it appears, and will be more or less abundant, not in proportion to the coldness of that body, but in proportion to the existing state of the air in regard to moisture. It is commonly supposed that the formation of dew produces cold, but like every other precipitation of water from the atmosphere, it must eventually produce heat.

2358. *Phenomena of dew.* Aristotle justly remarked, that dew appears only on calm and clear nights. Dr. Wells shews that very little is ever deposited in stormy circumstances; and that little only when the clouds are very high. It is never seen on nights both cloudy and windy; and if in the course of the night the weather, from being serene, should become dark and stormy dew which has been deposited will disappear. In calm weather if the sky be partially covered with clouds more dew will appear than if it were entirely uncovered. Dew probably begins in the country to appear upon grass in places shaded from the sun, during clear and calm weather, soon after the heat of the atmosphere has declined, and continues to be deposited through the whole night, and for a little after sunrise. Its quantity will depend in some measure on the proportion of moisture in the atmosphere, and is consequently greater after rain than after a long tract of dry weather; and in Europe, with southerly and westerly winds, than with those which blow from the north and the east. The direction of the sea determines this relation of the winds to dew for in Egypt, dew is scarcely ever observed except while the northerly or Etesian winds prevail. Hence also dew is generally more abundant in spring and autumn than in summer. It is always very copious on those clear nights which are followed by misty mornings, which show the air to be loaded with moisture, and a clear morning following a cloudy night determines a plentiful deposition of the retained vapour. When warmth of atmosphere is compatible with clearness, as is the case in southern latitudes, though seldom in our country, the dew becomes much more copious, because the air then contains more moisture. Dew continues to form with increased copiousness as the night advances, from the increased rarefaction of the ground.

2359. *Cause of dew.* Dew according to Aristotle, is a species of rain, formed in the lower atmosphere, in consequence of its moisture being condensed by the cold of the night into minute drops. Opinions of this kind, says Dr. Wells, are still entertained by many persons, among whom is the very ingenious Professor Leslie. (*Relat. of Heat and Moisture*, p. 37 and 132.) A fact, however first taken notice of by Gassius, who published his *Treatise on Dew* in 1775, proves them to be erroneous. For he found that bodies a little elevated in the air often become moist with dew while similar bodies lying on the ground, remain dry though necessarily from their position as liable to be wetted, by whatever falls from the heavens, as the former. The above notion is perfectly refuted by the fact, that metallic surfaces exposed to the air in a horizontal position remain dry while every thing around them is covered with dew. After a long period of drought, when the air was very still and the sky serene, Dr. Wells exposed to the sky 25 minutes before sunset, previously weighed parcels of wool and rswadown, upon a smooth, unpainted, and perfectly dry fir table, 5 feet long 3 broad, and nearly 3 in height, which had been placed, an hour before, in the sunshine in a large level grassfield. The wool, 13 minutes after sunset, was found to be  $14^{\circ}$  colder than the air and to have acquired no weight. The rswadown, the quantity of which was much greater than that of the wool, was at the same time  $15^{\circ}$  colder than the air and was also without any additional weight. In 30 minutes more the rswadown was  $14^{\circ}$  colder than the neighbouring air and was still without any increase of its weight. At the same time the grass was  $15^{\circ}$  colder than the air four feet above the ground. Dr. Wells, by a copious induction of facts derived from observation and experiment, establishes the proposition that bodies become colder than the neighbouring air before they are dewed. The cold therefore, which Dr. Wilson and M. Six conjectured to be the effect of dew now appears to be its cause. But what makes the terrestrial surface colder than the atmosphere? The radiation or projection of heat into free space. Now the researches of Professor Leslie and Count Rumford have demonstrated that different bodies project heat with very different degrees of force. In the operation of this principle therefore, conjoined with the power of a concave mirror of cloud, or any other awning, to reflect or throw down again those caloric emanations which would be dissipated in a clear sky, we shall find a solution of the most mysterious phenomena of dew.

2360. *Rain.* Luke Howard, who may be considered as our most accurate scientific meteorologist, is inclined to think that rain is in almost every instance the result of the electrical action of clouds upon each other.

2366. *Formation of rain.* Rain never descends till the transparency of the air ceases, and the invisible vapour becomes visible, when clouds form, and at length the drops fall; clouds, instead of forming gradually at once throughout all parts of the horizon, generate in a particular spot, and imperceptibly increase till the whole expanse is obscured.

2369. *The cause of rain is thus accounted for by Hutton and Dalton.* If two masses of air of unequal temperatures are, when saturated with vapour, intermixed by the ordinary currents of the winds, a precipitation ensues. If the masses are under saturation, then less precipitation takes place, or none at all, according to the degree. Also the warmer the air, the greater is the quantity of vapour precipitated in like circumstances. Hence the reason why rains are heavier in summer than in winter, and in warm countries than in cold.

2370. *The quantity of rain, taken at an annual mean, is the greatest at the equator, and it lessens gradually to the poles* at which there are fewer days of rain, the number increasing in proportion to the distance from them. From north latitude  $15^{\circ}$  to  $45^{\circ}$  the mean number of rainy days is 78, from  $45^{\circ}$  to  $46^{\circ}$  the mean number is 105; from  $46^{\circ}$  to  $50^{\circ}$ , 134 and from  $51^{\circ}$  to  $60^{\circ}$ , 181. Winter often produces a greater number of rainy days than summer though the quantity of rain is more considerable in the latter than in the former season at Petersburg rain and snow fall on an average 84 days of the winter and the quantity amounts to about five inches on the contrary, the summer produces eleven inches in about the same number of days. Mountainous districts are subject to great falls of rain among the Andes particularly, it rains almost incessantly, while the hot country of Egypt is consumed by endless drought. Dalton estimates the quantity of rain falling in England at 51 inches. The mean annual quantity of rain for the whole globe is 34 inches.

2371. *The cause why less rain falls in the first six months of the year than in the last six months is thus explained.* The whole quantity of water in the atmosphere in January is usually about three inches, as appears from the dew point, which is then about  $52^{\circ}$  now the force of vapours of that temperature is 0.2 of an inch of mercury, which is equal to 2.8 or three inches of water. The dew point in July is usually about  $56^{\circ}$  or  $59^{\circ}$ , corresponding to 0.5 of an inch of mercury which is equal to seven inches of water. Thus it is evident that, in the latter month, the atmosphere contains four inches of water more than in the former month. Hence, supposing the usual intermixture of currents of air in both the intervening periods to be the same, the rain ought to be four inches less in the former period of the year than the average, and four inches more in the latter period, making a difference of eight inches between the two periods, which nearly accords with the preceding observations.

2372. *The mean monthly and annual quantities of rain at various places, deduced from the average for many years, by Dalton, is given in the following Table* —

	London 30 years	Edinburgh 15 years	Glasgow 15 years	Manchester 20 years	Birmingham 20 years	Sheffield 20 years	Gloucester 17 years	Leicester 15 years	Nottingham 15 years	General Average
January	2.310	2.177	2.196	2.461	2.290	2.000	1.606	1.949	2.228	2.530
February	2.508	1.947	1.938	2.696	2.198	1.741	1.505	1.938	1.700	2.255
March	2.902	1.952	1.938	1.753	2.151	1.596	1.184	1.178	1.180	1.927
April	2.910	2.105	2.079	2.280	2.599	2.017	0.979	1.270	1.183	2.080
May	2.905	2.572	2.112	2.900	3.480	2.558	1.841	1.538	1.797	2.407
June	2.502	2.616	2.286	2.512	2.722	2.974	1.943	1.738	1.997	2.218
July	2.997	2.953	2.005	2.140	2.909	2.256	2.303	2.448	1.900	2.112
August	2.950	2.811	2.435	2.261	2.089	2.199	2.746	1.807	1.900	2.103
September	2.921	2.654	2.229	2.251	2.674	2.230	1.617	1.562	1.550	2.135
October	2.985	2.798	2.079	2.151	2.459	2.143	2.207	2.028	1.736	2.187
November	2.980	2.441	2.654	2.775	2.785	2.174	1.904	2.238	1.780	2.187
December	2.928	2.229	2.589	2.955	2.684	2.142	1.981	1.736	1.900	2.088
	32.140	34.131	27.604	32.714	33.934	32.919	21.351	30.685	18.940	33.977

2373. *Frost, being derived from the atmosphere, naturally proceeds from the upper parts of bodies downwards; so the longer a frost is continued, the thicker the ice becomes upon the water in ponds, and the deeper into the earth the ground is frozen.* In about 16 or 17 days' frost, Boyle found it had penetrated 14 inches into the ground. At Moscow, in a hard season, the frost will penetrate two feet deep into the ground and Captain James found it penetrated 10 feet deep in Charlton Island, and the water in the same island was frozen to the depth of six feet. Schaffer assures us, that in Sweden the frost pierces two cubits (a Swedish ell) into the earth, turning what moisture is found there into a whitish substance like ice; and into standing water three ells or more. The same author also mentions sudden cracks or rifts in the ice of the lakes of Sweden, nine or ten feet deep, and many leagues long the rupture being made with a noise not less

loud than if many guns were discharged together. By such means, however, the fishes are furnished with air, so that they are rarely found dead.

2374. *The history of frost furnishes very extraordinary facts. The trees are often scorched and burnt up, as with the most excessive heat, in consequence of the separation of water from the air which is therefore very drying. In the great frost in 1683, the trunks of oak, ash, walnut, and other trees, were miserably split and cleaved, so that they might be seen through, and the cracks often attended with dreadful noises like the explosion of fire-arms.*

2375. *Hail is generally defined as frozen rain. It differs from it in that the hailstones for the most part are not formed of single pieces of ice, but of many little spherules agglutinated together: neither are these spherules all of the same consistence, some of them being hard and solid, like perfect ice; others soft, and mostly like snow hardened by a severe frost. Hailstone has sometimes a kind of core of this soft matter, but more frequently the core is solid and hard, while the outside is formed of a softer matter. Hailstones assume various figures, being sometimes round, at other times pyramidal, crested, angular, thin or flat, and sometimes stellated with six radii like the small crystals of snow. Natural historians furnish us with various accounts of surprising showers of hail, in which the hailstones were of extraordinary magnitude.*

2376. *Snow is formed by the freezing of the vapours in the atmosphere. It differs from hail and hoar frost, in being as it were crystallised while they are not. As the flakes fall down through the atmosphere, they are continually joined by more of these radiated spicula, and they increase in bulk like the drops of rain or hailstones. The lightness of snow, although it is firm ice, is owing to the excess of its surface in comparison with the matter contained under it: as gold itself may be extended in surface till it will ride upon the least breath of air. The whiteness of snow is owing to the small particles into which it is divided: for ice when pounded will become equally white.*

2377. *Snow is of great use to the vegetable kingdom. Were we to judge from appearance only we might imagine that, so far from being useful to the earth, the cold humidity of snow would be detrimental to vegetation: but the experience of all ages asserts the contrary. Snow particularly in those northern regions where the ground is covered with it for several months, fructifies the earth, by guarding the corn or other vegetables from the intenser cold of the air and especially from the cold piercing winds. It has been a vulgar opinion, very generally received, that snow fertilises the land on which it falls more than rain, in consequence of the nitrous salts which it is supposed to acquire by freezing: but it appears from the experiments of Margraaf, in the year 1771 that the chemical difference between rain and snow-water is exceedingly small: that the latter contains a somewhat less proportion of earth than the former: but neither of them contains either earth, or any kind of salt, in any quantity which can be sensibly efficacious in promoting vegetation. The peculiar agency of snow as a fertiliser in preference to rain, may be ascribed to its furnishing a covering to the roots of vegetables, by which they are guarded from the influence of the atmospherical cold, and the internal heat of the earth is prevented from escaping. Different vegetables are able to preserve life under different degrees of cold, but all of them perish when the cold which reaches their roots is extreme. Providence has, therefore in the coldest climates, provided a covering of snow for the roots of vegetables, by which they are protected from the influence of the atmospherical cold. The snow keeps in the internal heat of the earth, which surrounds the roots of vegetables, and defends them from the cold of the atmosphere.*

2378. *Ice is water in the solid state, during which the temperature remains constant, being 32 degrees of the scale of Fahrenheit. Ice is considerably lighter than water: namely, about one eighth part, and this increase of dimensions is acquired with prodigious force, sufficient to burst the strongest iron vessels, and even pieces of artillery. Congelation takes place much more suddenly than the opposite process of liquefaction: and of course, the same quantity of heat must be more rapidly extricated in freezing than it is absorbed in thawing: the heat thus extricated being disposed to fly off in all directions, and little of it being retained by the neighbouring bodies, more heat is lost than is gained by the alternation: so that where ice has once been formed, its production is in this manner redoubled.*

2379. *The northern ice extends during summer about 50° from the pole: the southern 18° or 20°; in some parts even 30°; and floating ice has occasionally been found in both hemispheres as far as 40° from the poles, and sometimes, as it has been said, even in latitude 41° or 43°. Between 54° and 60° south latitude, the snow lies on the ground, at the sea-side, throughout the summer. The line of perpetual congelation is three miles above the surface at the equator where the mean heat is 84° at Teneriffe, in latitude 28°, two miles. In the latitude of London, a little more than a mile: and in latitude 50° north, only 1280 feet. At the pole, according to the analogy deduced by Kurwan, from Meyer's Formula, and which is not however found to agree very exactly with what takes place, from a comparison of various observations, the mean temperature should be 51°*

In London the mean temperature is  $50^{\circ}$ ; at Rome and at Montpellier, a little more than  $60^{\circ}$ ; in the island of Madeira,  $70^{\circ}$ ; and in Jamaica,  $80^{\circ}$ .

2390. *Wind.* Were it not for this agitation of the air, putrid effluvia arising from the habitations of man, and from vegetable substances, besides the exhalations from water, would soon render it unfit for respiration, and a general mortality would be the consequence. The prevailing winds of our own country which were ascertained by order of the Royal Society of London, at London, are,

Winds.	Days.	Winds.	Days.	Winds.	Days.
North-west	118	West	15	South	18
North-east	68	South-east	38	North	16
North-west	80	East	56		

The westerly winds blow more upon an average in each month of the year than any other, particularly in July and August; the north-east wind prevails during January, March, April, May, and June, and is most unfrequent in February, July, September, and December the north-west occurring more frequently from November to March, and less so in September and October than in any other months.

2391. *Near Glasgow*, the average is stated as follows —

Winds.	Days.	Winds.	Days.
South-west	176	North-east	104
North-west	40	South-east	67

2392. *In Ireland*, the prevailing winds are the west and south-west.

2393. *The different degrees of motion of wind* next excite our attention, and it seems almost superfluous to observe, that it varies in gradation from the mildest seephy, which plays upon the leaves of plants, gently undulating them, to the furious tempest, calculated to inspire horror in the breast of the most callous. It is also a remarkable fact, that violent currents of air pass along as it were, within a line, without sensibly agitating that beyond them. An instance of the fury of the wind being bounded "by a line" occurs in the hurricanes of America, where its devastating course is often accurately marked in the forests for a great extent in one direction.

2394. *Causes of wind.* There are many circumstances attending the operations of the air which we term wind, which serve for a basis for well-founded conjectures, and those, united to the result of daily observation, render the explanation of its phenomena tolerably satisfactory.

2395. *It must be clear in the most common capacity* that as the rays of the sun descend perpendicularly on the surface of the earth under the torrid zone, that part of it which receives a greater proportion of heat than those parts where they fall obliquely; the heat thus acquired communicates to the air which it warms, and causes it to ascend, and the vacuum occasioned by this operation is immediately filled by the still air from the north and south. The diurnal motion of the earth gradually lessens to the poles from the equator, at which point it moves at the rate of fifteen geographical miles in a minute and this motion is communicated to the atmosphere in the same degree, but if part of the atmosphere were conveyed independently to the equator from latitude  $30^{\circ}$  it would not directly acquire the equatorial velocity, consequently the ridges of the earth must meet it, and give it the appearance of an east wind. The effect is similar upon the cold air proceeding from the north and south, and this similarity must be admitted to extend to each place particularly heated by the beams of the sun. The moon, being a large body situated comparatively near the earth is known to affect the atmosphere and thus, and the continual shifting of the point of the earth's surface over which the sun is vertical, to the west, are given as the causes of the tides and of the trade winds. The moon's revolutions, by pressing the atmosphere upon the sea, cause the flux and reflux which we call tides; it cannot, therefore, be doubted that some of the winds we experience are caused by the moon's motion.

2396. *The regular motion of the atmosphere* known by the name of *land and sea breezes*, may be explained by the effects of refraction. The air heated over the land rises up, because rarefied, and its place is supplied by the cooler air which flows in from the sea. This produces the *sea breeze*; at sunset, the equilibrium is first restored, but as the earth cools faster by radiation than the water the air over it becomes colder than that over the sea, especially if there be mountains in the vicinity; the air over the land then displaces the light air from the sea, and thus the *land breeze* is formed. Granting that the attraction of the moon and the diurnal movement of the sun affect our atmosphere there cannot be a doubt but a westward motion of the air must prevail within the boundaries of the trade-winds, the consequence of which is an easterly current on each side. From this, then, it proceeds that south-west winds are so frequent in the western parts of Europe, and over the Atlantic Ocean. Kirwan attributes our constant north-west winds, particularly during winter, to an opposite current prevailing between the coast of Malabar and the Malaccas at the same period. This, he adds, must be supplied from regions close to the pole, which must be recruited in its turn from the countries to the south of it, in the western parts of our hemisphere.

2397. *The terrible winds* cannot be so readily accounted for yet it is evident, that though they seem the effect of capricious causes, they depend upon a regular system, arranged by the great Author of nature. That accurate and successful observer of part of his works, the celebrated Franklin, discovered in 1760, that winds originate at the various points towards which they blow. This philosopher had hoped to observe an eclipse of the moon at Philadelphia, but was prevented by a north-east storm, that commenced at seven in the evening. This he afterwards found did not occur at Boston till eleven, and upon enquiry he had reason to suppose, it passed to the north-east at the rate of about 100 miles an hour. The manner in which he accounts for this extraordinary proceeding is so satisfactory that we shall give it in his own words, particularly as his assertions are supported by recent observations, both in America and Scotland. He argued thus:—"I suppose a long canal of water, stopped at the end by a gate. The water is at rest till the gate is opened; then it begins to move out through the gate, and the water next the gate is put in motion and moves on towards the gate; and so on successively till the water at the head of the canal is in motion, which it is last of all. In this case all the water moves toward the gate, but the successive burst of impelling the motion and in the contrary way. First from the gate back to the head of the canal. Thus to produce a north-east storm, I suppose some great rarefaction of the air in or near the Gulf of Mexico; the air rising thence has its place supplied by the next more northern, cooler and therefore denser and heavier air; a successive current is formed, to which our coast and inland mountains

give a north-east direction." According to the observations made by Captain Cook, the north-east winds prevail in the Northern Pacific Ocean during the same spring months they do with us, from which facts it appears the cold air from America and the north of Europe flows at that season into the Pacific and Atlantic Oceans.

2389. *Other descriptions of clouds may arise from a variety of causes. The atmosphere has been ascertained to be composed of air vapour and carbonic acid and water, and as it is well known that these frequently change their aerial form, and combine with different substances, and the reverse, consequently partial winds and accumulations must continually occur which occasion winds of different degrees of violence, continuance, and direction.*

2389. *The principal electrical phenomena of the atmosphere are thunder and lightning.*

2390. *Thunder is the noise occasioned by the explosion of a flash of lightning passing through the air or it is that noise which is excited by a sudden explosion of electrical clouds, which are therefore called thunder-clouds.*

2391. *The rattling in the noise of thunder which makes it seem as if it passed through arches, is probably owing to the sound being excited among clouds hanging over one another between which the exploded air passes irregularly.*

2392. *The explosion, if high in the air and remote from us, will do no mischief, but when near it may; and it has, in a thousand instances, destroyed trees, animals, &c. This proximity or small distance may be estimated nearly by the interval of time between seeing the flash of lightning and hearing the report of the thunder, reckoning the distance after the rate of 1145 feet to a second of time, or 34 seconds to the mile. Dr. Wallis observes, that commonly the distance between the two is about seven seconds, which, at the rate above-mentioned, gives the distance almost two miles. but sometimes it comes in a second or two which argues the explosion very near to us, and even among us; and in such cases, the doctor assures us, he has sometimes foretold the mischief that happened.*

2393. *Season of thunder. Although in this country thunder may happen at any time of the year, yet the months of July and August are those in which it may almost certainly be expected. Its devastations are of very uncertain continuance; sometimes only a few peals will be heard at any particular place during the whole season at other times the storm will return, at intervals of three or four days, for a month, six weeks, or even longer; not that we have violent thunder in this country directly vertical in any one place so frequently in any year, but in many seasons it will be perceptible that thunder-clouds are formed in the neighbourhood even at these short intervals. Hence it appears, that during this particular period, there must be some natural cause operating for the production of the phenomenon which does not take place at other times. This cannot be the mere heat of the weather, for we have often a long tract of hot weather without any thunder; and besides though not common thunder is sometimes heard in the winter also. As therefore the heat of the weather is common to the whole summer whether there is thunder or not, we must look for the causes of it in those phenomena, whatever they are, which are peculiar to the months of July, August, and the beginning of September. Now it is generally observed, that from the month of April, an east or south-east wind generally takes place and continues with little interruption till towards the end of June. At that time, sometimes sooner and sometimes later a westerly wind takes place, but as the causes producing the east wind are not removed, the latter opposes the west wind with its whole force. At the place of meeting, there are naturally a most vehement pressure of the atmosphere and friction of its parts against one another; a calm ensues, and the vapours brought by both winds begin to collect and form dark clouds, which can have little motion either way, because they are pressed almost equally on all sides. For the most part, however the west wind prevails, and what little motion the clouds have is towards the east whence, the common remark in this country that thunder-clouds move against the wind." But this is by no means universally true for if the west wind happens to be excited by any temporary cause before the natural period when it should take place, the east wind will very frequently get the better of it; and the clouds, even although thunder is produced, will move westward. Yet in either case, the motion is so slow that the most superficial observers cannot help taking notice of a considerable resistance in the atmosphere.*

2394. *Thunderbolts. When lightning acts with extraordinary violence, and breaks or shatters any thing it is called a thunderbolt, which the vulgar to fit it for such effects, suppose to be a hard body and even a stone. But that we need not have recourse to a hard solid body to account for the effects commonly attributed to the thunderbolt, will be evident to any one who considers those of gunpowder and the several chemical fulminating powders, but more especially the astonishing powers of electricity when only collected and employed by human art, and much more when directed and exercised in the course of nature. When we consider the known effects of electrical explosions, and those produced by lightning, we shall be at no loss to account for the extraordinary operations vulgarly ascribed to thunderbolts. As stones and bricks struck by lightning are often found in a vitrified state, we may reasonably suppose, with Beccaria, that some stones in the earth, having been struck in this manner gave occasion to the vulgar opinion of the thunderbolt.*

2395. *Thunder-clouds are those clouds which are in a state fit for producing lightning and thunder. The first appearance of a thunder-storm, which usually happens when there is little or no wind, is one dense cloud, or mass, increasing very fast in size, and rising into the higher regions of the air. The lower surface is black, and nearly level; but the upper finely arched, and well defined. Many of these clouds often seem piled upon one another all arched in the same manner; but they are continually uniting, swelling, and extending their arches. At the time of the rising of this cloud, the atmosphere is commonly full of a great many separate clouds, which are motionless, and of odd whimsical shapes; all these, upon the appearance of the thunder-cloud, draw towards it, and become more uniform in their shape as they approach, till, coming very near the thunder-cloud, their limbs mutually stretch towards one another, and they immediately coalesce into one uniform mass. Sometimes the thunder-cloud will swell, and increase very fast, without the conjunction of any additional clouds; the vapours in the atmosphere forming themselves into clouds whenever it passes. Some of the additional clouds appear like white fringes, at the skirts of the thunder-cloud, or under the body of it; but they keep continually growing darker and darker, as they approach to unite with it. When the thunder-cloud is grown to a great mass, its lower surface is often ragged, particular parts being detached towards the earth, but still connected with the rest. Sometimes the lower surface swells into various large protuberances, hanging untidily downward, and sometimes one whole side of the cloud will have an inclination to the earth and the extremity of it will nearly touch the ground. When the eye is under the thunder-cloud, after it is grown large and well formed, it is seen to sink lower and to darken prodigiously; at the same time that a number of small additional clouds (the origin of which can never be perceived) are seen in a rapid motion, drifting about in very uncertain directions under it. While these clouds are agitated with the most rapid motions, the rain commonly falls in the greatest plenty and if the agitation be exceedingly great, it commonly hail.*

2396. *Lightning. While the thunder-cloud is swelling, and extending its branches over a large tract of country the lightning is seen to dart from one part of it to another, and often to illuminate its whole mass. When the cloud has acquired a sufficient extent, the lightning strikes between the cloud and the earth, in two opposite places, the path of the lightning lying through the whole body of the cloud and its branches. The*

longer the lightning continues, the less dense does the cloud become, and the less dark its appearance; till at length it breaks in different places, and shows a clear sky. These thunder-clouds are said to be sometimes in a positive as well as a negative state of electricity. The electricity continues longer of the same kind, in proportion as the thunder-cloud is simple and uniform in its direction; but when the lightning changes its place, there commonly happens a change in the electricity of the atmosphere over which the clouds passed. It changes suddenly after a very violent flash of lightning; but gradually when the lightning is moderate, and the progress of the thunder-cloud slow.

2397 *Lightning is an electrical explosion or phenomenon.* Flashes of lightning are usually seen in broad and undefined masses; when their path appears angular or zigzag, they are reckoned most dangerous. They strike the highest and most pointed objects in preference to others, as hills, towers, spires, masts of ships, &c.; as all pointed conductors receive and throw off the electric fluid more readily than those that are terminated by flat surfaces. Lightning is observed to take and follow the roundest and best conductor; and the same is the case with electricity in the discharge of the Leyden phial; whence it is inferred, that in a thunder-storm it would be safer to have one's clothes wet than dry. Lightning burns, dissolves metals, rends some bodies, sometimes strikes persons blind, destroys animal life, destroys magnets of their virtue, or reverses their poles; and all these are well known properties of electricity.

2398. *With regard to places of safety in times of thunder and lightning.* Dr. Franklin's advice is to sit in the middle of a room, provided it be not under a metal stove suspended by a chain, sitting on one chair and tying the feet on another. It is still better, he says, to bring two or three mattresses or beds into the middle of the room, and folding them double, to place the chairs upon them; for as they are not so good conductors as the walls, the lightning will not be so likely to pass through them. But the safest place of all is in a hammock hung by silk cords, at an equal distance from all the sides of the room. Dr. Franklin observes, that the place of most perfect safety must be the taller and especially the middle of it; for when a person is lower than the surface of the earth the lightning must strike it before it can possibly reach him. In the fields, the place of safety is within a few yards of a tree, but not quite near it. Becerra cautions persons not always to trust too much to the neighbourhood of a higher or better conductor than their own body, since he has repeatedly found that the lightning by no means descends in one undivided track, but that bodies of various kinds conduct their share of it at the same time, in proportion to their quantity and conducting power.

#### SECT. II. *Of the Means of Prognosticating the Weather*

2399. *The study of atmospheric changes has, in all ages, been more or less attended to by men engaged in the culture of vegetables, or the pasturage of animals; and we, in this country are surprised at the degree of perfection to which the ancients attained in this knowledge; but it ought to be recollected, that the study of the weather in the countries occupied by the ancients, as Egypt, Greece, Italy, and the continent of Europe, is a very different thing from its study in an island situated like ours. It is easy to forecast weather in countries where months pass away without rain or clouds, and where some weeks together, at stated periods, are as certainly seasons of rain or snow. It may be asserted with truth, that there is a greater variety of weather in London in one week, than in Rome, Moscow, or Petersburg in three months. It is not, therefore, entirely a proof of our degeneracy, or the influence of our artificial mode of living, that we cannot predict the weather with such certainty as the ancients; but a circumstance rather to be accounted for from the peculiarities of our situation.*

2400. *A variable climate, such as ours, admits of being studied, both generally and locally; but it is a study which requires habits of observation and reflection like all other studies; and to be brought to any useful degree of perfection must be attended to, not as it commonly is, as a thing by chance, and which every body knows, or is fit for, but as a serious undertaking. The weather may be foretold from natural data, artificial data, and from precedent.*

2401. *The natural data for this study are, 1. The vegetable kingdom, many plants shutting or opening their flowers, contracting or expanding their parts, &c. on approaching changes in the humidity or temperature of the atmosphere. 2. The animal kingdom, most of those familiar to us exhibiting signs on approaching changes, of which these by cattle and sheep are more especially remarkable; and hence shepherds are generally, of all others, the most correct in their estimate of weather. 3. The mineral kingdom, stones, earths, metals, salts, and water of particular sorts, often showing indications of approaching changes. 4. Appearances of the atmosphere, the moon, the general character of seasons, &c. The characters of clouds, the prevalence of particular winds, and other signs are very commonly attended to.*

2402. *The influence of the moon on the weather has, in all ages, been believed by the generality of mankind; the same opinion was embraced by the ancient philosophers; and several eminent philosophers of later times have thought the opinion not unworthy of notice. Although the moon only acts (as far at least as we can ascertain) on the waters of the ocean by producing tides, it is nevertheless highly probable, according to the observations of Lambert, Toulko, and Cotte, that in consequence of the lunar influence, great variations do take place in the atmosphere, and consequently in the weather. The following principles will show the grounds and reasons for their embracing the received notions on this interesting topic:—*

2403. *There are two situations in the moon's orbit when she must particularly exert her influence on the atmosphere; and when, consequently changes of the weather must readily take place. These are, 1st. The new, and 2d. The full moon, when she exerts her influence in conjunction with, or in opposition to the sun.*

3d and 4th. The quadratures, or those aspects of the moon when she is 90° distant from the sun or when she is in the middle point of her orbit, between the points of conjunction and opposition, namely, in the first and third quarters.

5th. The perigee, and 6th. The apogee or those points of the moon's orbit, in which she is at the least and greatest distance from the earth.

7th and 8th. The two passages of the moon over the equator, one of which Tardieu calls the moon's *ascend.* and the other the moon's *descending equinox* or the two *solstices* as De la Lande terms them.

9th. The several lunations, when the moon approaches as near as she can in each lunation (or period between one new moon and another) to our zenith (that point in the horizon which is directly over our heads).

10th. The several lunations, when she is at the greatest distance from our zenith for the action of the moon varies greatly according to her obliquity. With these ten points Toaldo compared a table of forty eight years' observations. The result is, that the probability, that the weather will change at a certain period of the moon, are in the following proportions. New moon, 5 to 1. First quarter 5 to 2. Full moon, 5 to 2. Last quarter 5 to 6. Perigee 7 to 1. Apogee 4 to 1. Ascending equinox, 13 to 4. Northern lunation 11 to 4. Descending equinox, 11 to 4. Southern lunation, 3 to 1.

9994. That the new moon will bring with it a change of weather is in the doctrine of chances as 5 to 1. Each situation of the moon alters the state of the atmosphere which has been accustomed by the preceding one and it seldom happens that any change in the weather takes place without a change in the lunar situation. These situations are combined, on account of the inequality of their revolutions, and the greatest effect is produced by the union of the syzygies, or the conjunction and opposition of a planet with the sun with the apogees, or points in the orbit of planets, in which they are at the greatest and least distance from the sun or earth. The proportions of their powers to produce variations are as follows. — New moon coinciding with the perigee, 13 to 1. Ditto, with the apogee, 7 to 1. Full moon coinciding with the perigee 10 to 1. Ditto, with the apogee, 8 to 1. The combination of these situations generally occasions storms and tempests and this perturbing power will always have the greater effect, the nearer these combined situations are to the moon's passage over the equator particularly in the months of March and September. At the new and full moons, in the months of March and September, and even at the solstices, especially the winter solstice the atmosphere assumes a certain character, by which it is distinguished for three and sometimes six months. The new moons which produce no change in the weather are those that happen at a distance from the equator. As it is perfectly true that each situation of the moon alters that state of the atmosphere which has been produced by another, it is also observed that many situations of the moon are favourable to good and others to bad weather.

9995. The situations of the moon, *favourable to bad weather* are the perigee new and full moon, passage of the equator and the northern lunation. Those belonging to the former are, the apogee, quadratures, and the southern lunation. Changes of the weather seldom take place on the very days of the moon's situation, but either precede or follow them. It has been found by observation that the changes affected by the lunar situations in the six winter months precede, and in the six summer months follow them.

9996. The *octants*. Besides the lunar situations to which the above observations refer attention must be paid also to the fourth day before new and full moon which days are called the octants. At these times the weather is inclined to changes and it may be easily seen, that there will follow at the next lunar situation Virgil calls this fourth day a very sure prophet. If on that day the horns of the moon are clear and well defined, good weather may be expected, but if they are dull, and not clearly marked on the edges, it is a sign that bad weather will ensue. When the weather remains unchanged on the fourth fifth and sixth day of the moon, we may conjecture that it will continue so till full moon even sometimes till the next new moon and in that case the lunar situations have only a very weak effect. Many observers of nature have also remarked, that the approach of the lunar situations is somewhat critical for the sick. According to Dr Herschel, the nearer the time of the moon's entrance at full, change or quarters, is to midnight (that is within two hours before and after midnight) the more fair the weather is in summer, but the nearer to noon the less fair. Alas, the moon's entrance, as full, change, or quarters, during six of the afternoon hours, viz. from four to ten may be followed by fair weather but this is mostly dependent on the wind. The same entrance during all the hours after midnight, except the first two, is unfavourable to fair weather the like, nearly may be observed in winter.

9997. The *artificial data* are the barometer, hygrometer, rain-gauge, and thermometer.

9998. By means of the *barometer* Taylor observes, we are enabled to regain, in some degree at least, that foreknowledge of the weather which the ancients unquestionably did possess though we know not the data on which they founded their conclusions. Chaptal considers that the value of the barometer as an indicator of the approaching weather, is greater than that of the lunar knowledge of the most experienced countryman, and indeed of all other means put together (*Agriculture appliquée à Chaux, &c.*) We shall therefore annex such rules as have hitherto been found most useful in ascertaining the changes of the weather by means of the barometer.

9999. The *rising of the mercury presages, in general, fair weather*, and its falling foul weather, as rain, snow, high winds, and storms.

9910. The *sudden falling of the mercury foretells thunder* in very hot weather especially if the wind is south.

9911. The *rising in winter indicates frost* and in frosty weather, if the mercury falls three or four divisions, there will follow a thaw but if it rises in a continued frost, snow may be expected.

9912. When *fair weather happens soon after the falling of the mercury* it will not be of long duration nor are we to expect a continuance of fair weather. When it soon succeeds the rising of the quicksilver.

9913. If *in fine weather the mercury rises considerably* and continues rising for two or three days before the foul weather is over, a continuance of fair weather may be expected to follow.

9914. In *fair weather, when the mercury falls much and low and continues falling for two or three days before rain comes, much wet must be expected* and probably high winds.

9915. The *unequal motion of the mercury indicates changeable weather*.

9916. Respecting the words engraved on the register plate of the barometer, it may be observed, that their exact correspondences with the state of the weather cannot be strictly relied upon, though they will in general agree with it as to the mercury rising and falling. The engraved words are to be regarded only as indicating probable consequences of the varying pressure of the atmosphere. The barometer, in fact, only shows the pressure of the aerial column, and the agitations of the atmosphere are merely events which experience has shown usually to accompany the sinking of the mer-

capital column, but are not necessarily connected with fluctuations of pressure. The words deserve to be particularly noticed when the mercury removes from "changeable" upwards; as those on the lower part should be adverted to, when the mercury falls from "changeable" downwards. In other cases, they are of no use, for, as its rising in any part forebodes a tendency to fair, and its falling to foul weather, it follows that, though it descend in the tube from settled to fair, it may nevertheless be attended with a little rain, and when it rises from the words "much rain" to "rain" it shows only an inclination to become fair, though the wet weather may still continue in a less considerable degree than it was when the mercury began to rise. But if the mercury, after having fallen to "much rain," should ascend to "changeable," it foretells fair weather though of a shorter continuance than if the mercury had risen still higher; and so, on the contrary, if the mercury stood at "fair" and descends to "changeable," it announces foul weather, though not of so long continuance as if it had fallen lower.

2417 *Opacity of the surface of the mercury.* Persons who have occasion to travel much in the winter and who are doubtful whether it will rain or not, may easily ascertain this point by the following observation:—A few hours before he departs, let the traveller notice the mercury in the upper part of the tube of the barometer if rain is about to fall, it will be indented, or concave, if otherwise, convex or protuberant.

2418 *Barometer in spring.* Towards the end of March, or more generally in the beginning of April, the barometer sinks very low with bad weather after which it seldom falls lower than 29 degrees 5 minutes till the latter end of September or October, when the quicksilver falls again low with stormy winds, for then the winter constitution of the air takes place. From October to April, the great falls of the barometer are from 29 degrees 5 minutes to 28 degrees 5 minutes, and sometimes lower whereas, during the summer constitution of the air, the quicksilver seldom falls lower than 29 degrees 5 minutes. It therefore follows that a fall of one tenth of an inch, during the summer, is as sure an indication of rain, as a fall of between two and three tenths is in the winter.

2419. The hygrometer is of various sorts, but cord, fiddle-string, and most of the substances commonly used, become sensibly less and less accurate, so as at length not to undergo any visible alteration from the different states of the air, in regard to dryness or moisture. The most common of all barometers is that formed of the beard of the wild oat, *Avena sativa*.

2420. A sponge makes a good hygrometer on this account, as being less liable to be changed by use than cord. To preserve the sponge, first wash it in water and when dry wash it again in water whereon sal ammoniac or salt of tartar has been dissolved; and let it dry again. Now if the air becomes moist, the sponge will grow heavier, and if dry it will become lighter.

2421. Oil of sweet is found to grow sensibly lighter or heavier in proportion to the less or greater quantity of moisture it imbibes from the air. The alteration is so great, that it has been known to change its weight from three drachms to nine. The other acid oils, or as they are usually called, spirits, or oil of tartar *per deliquium*, may be substituted for the oil of vitriol.

2422. *Steel-yard's hygrometer.* In order to make a hygrometer with those bodies which acquire or lose weight in the air place such a substance in a scale on the end of a steel-yard with a counterpoise which shall keep it in equilibrium in this weather; the other end of the steel-yard, rising or falling, and pointing to a graduated index, will show the changes.

2423. *Lead and plummet.* If a line be made of good well dried whipcord, and a plummet be fixed to the end of it, and the whole be hung against a wall-plate, and a line be drawn under it, exactly where the plummet reaches, in very moderate weather it will be found to rise above such line, and to sink below it when the weather is likely to become fair.

2424. *The hair hygrometer of Sennerus, and the whalebone hygrometer* originally invented by De Linc, are esteemed two of the best now in use.

2425. *The best and simplest, only perfect hygrometer* is that of professor Leslie. It consists of a glass tube, with a ball blown at each end (fig. 224.) and filled with air. A coloured liquid fills one leg of the siphon; the ball on the opposite limb, smoothly coated with tissue paper, is the evaporating surface; this is kept perpetually moist by means of a thread passing from a jar with water as high as the instrument to the covered ball. The cold produced by evaporation causes the air in that ball to contract, and the column of liquid is forced into that stem by the elasticity of the air included in the naked ball. This rise is exactly proportional to the dryness of the air (T)

2426 *The rain-gauge, pluviometer, or hyetometer,* is a machine for measuring the quantity of rain that falls.

209

2427 *A hollow cylinder* forms one of the best-constructed rain-gauges; it has within it a cork ball attached to a wooden stem (fig. 209.), which passes through a small opening at the top, on which is placed a large funnel. When this instrument is placed in the open air in a free place, the rain that falls within the circumference of the funnel will run down into the tube and cause the cork to float, and the quantity of water in the tube may be seen by the height to which the stem of the float is raised. The stem of the float is so graduated as to show by its divisions the number of perpendicular inches of water which fill on the surface of the earth since the last observation. After every observation the cylinder must be emptied.

2428. A copper funnel forms another very simple rain-gauge: the area of the opening must be exactly ten square inches. Let this funnel be fixed in a bottle, and the quantity of rain caught is ascertained by multiplying the weight in ounces by 173, which gives the depth in inches and parts of an inch.

2429. In fixing these gauges, care must be taken that the rain may have free access to them, hence the tops of buildings are usually the best places, though some conceive that the nearer the rain-gauge is placed to the ground the more rain it will collect.

2430. In order to compare the quantities of rain collected in pluviometers at different places, the instruments should be fixed at the same heights above the ground in all such places, because, at different heights, the quantities are always different, even at the same place.

2431. *Thermometer.* As the weight of the atmosphere is measured by the barometer so the thermometer shows the variations in the temperature of the weather for every change of the weather is attended with a change in the temperature of the air, which a thermometer placed in the open air will point out, sometimes before any alteration is perceived in the barometer.

2432. The scales of different thermometers are as follows. — In Fahrenheit's the freezing point is 32 degrees, and the boiling point 212 degrees. In Reaumur's the freezing point is 0, and the boiling point 80 degrees. In the centigrade thermometer which is generally used in France, and is the same as that of Celsius, which is the thermometer of Sweden, the freezing point is 0, and the boiling point 100 degrees. As a rule for comparing or reducing these scales, it may be stated, that 1 degree of Reaumur's scale contains 2 degrees of Fahrenheit, and to convert the degrees of the one to the other the rule is to multiply by 9, divide by 8, and add 32. One degree of the centigrade scale is equal to one degree and eight tenths of Fahrenheit, and the rule here is to multiply by 9, divide by 5, and add 32. Any of these thermometers may be proved by immersing it in pounded ice for the freezing point, and in boiling water for the boiling point, and if the space between these points is equally divided, the thermometer is correct.

2433. The study of the weather from precedent, affords useful hints as to the character of approaching seasons. From observing the general character of seasons for a long period, certain general results may be deduced. On this principle, Kirwan, on comparing a number of observations taken in England from 1677 (*Trans. Ir. Acad.* v. 20.) to 1789 a period of 112 years, found

That when there has been no storm before or after the vernal equinox the ensuing summer is generally dry, at least five times in six.

That when a storm happens from an easterly point either on the 19th, 20th or 21st of May the succeeding summer is generally dry at least four times in five.

That when a storm arises on the 25th, 26th or 27th of March, and not before in any point, the succeeding summer is generally dry, four times in five.

If there be a storm at S. W. or W. S. W. on the 19th, 20th, 21st, or 22d of March, the succeeding summer is generally wet, five times in six.

In this country winters and springs, if dry, are most commonly cold; if moist, warm: on the contrary dry summers and autumns are usually hot and moist summers cold so that, if we know the moistness or dryness of a season we can form a tolerably accurate judgment of its temperature. In this country also, it generally rains less in March than in November in the proportion of 7 to 12. It generally rains less in April than October in the proportion of 1 to 2 nearly at a medium. It generally rains less in May than September: the chances that it does so are at least 4 to 3. But, when it rains plentifully in May as 16 inches or more, it generally rains but little in September and when it rains one inch or less, in May it rains plentifully in September.

2434. The probabilities of particular seasons being followed by others have been calculated by Kirwan and although his rules chiefly relate to the climate of Ireland, yet as there exists but little difference between that island and Great Britain, in the general appearance of the seasons, we shall mention some of his conclusions.

In forty-one years there were 6 wet springs, 22 dry and 13 variable; 20 wet summers, 16 dry and 5 variable; 11 wet autumns, 11 dry and 19 variable.

2435. A season is accounted wet, when it contains two wet months. In general, the quantity of rain, which fall in dry seasons, is less than five inches, in wet seasons more variable seasons are those, in which there fall between 30 lbs. and 86 lbs., a pound being equal to 1.57639 of an inch.

2436. January is the coldest month in every latitude, and July is the warmest month in all latitudes above 48 degrees: in lower latitudes, August is generally the warmest.

The difference between the hottest and coldest months increases in proportion to the distance from the equator. Every habitable latitude enjoys a mean heat of 60 degrees for at least two months; which heat is necessary for the production of corn.

### SECT. III. Of the Climate of Britain

2437. The climate of the British isles, relatively to others in the same latitude, is temperate, humid, and variable. The moderation of its temperature and its humidity are owing to our being surrounded by water, which being less affected by the sun than the earth, imbibes less heat in summer, and, from its fluidity is less easily cooled in winter.

As the sea on our coast never freezes, its temperature must always be above 35° or 34° and hence, when air from the polar regions at a much lower temperature passes over it, that air must be in some degree heated by the radiation from the water. On the other hand, in summer, the warm currents of air from the south necessarily give out

part of their heat in passing over a surface so much lower in temperature. The variable nature of our climate is chiefly owing to the unequal breadth of watery surfaces which surround us, on one side, a channel of a few leagues in breadth on the other, the Atlantic Ocean. The temperature of the British seas rarely descends below  $33^{\circ}$  or  $34^{\circ}$ .

2438. *The British climate varies materially within itself* some districts are dry, as the east; others moist, as the west coast in the northern extremity, dry cold, and windy; in the south warm and moist. Even in moist districts some spots are excessively dry, as part of Wiltshire, from the influence of the Isle of Man in warding off the watery clouds of the Atlantic and, in dry districts, some spots are moist, from the influence of high mountains in attracting and condensing clouds charged with watery vapour. The mean temperature of London equals  $50^{\circ}$   $56^{\circ}$  that of Edinburgh equals  $47^{\circ}$   $64^{\circ}$ ; and the probable mean temperature of all Britain will equal  $48^{\circ}$ . The usual range of the barometer is within three inches. The mean annual rain is probably about 32 inches. The climate is variable, and subject to sudden alternations of heat and cold, which are supposed to render pulmonary complaints common with us but on the whole it is healthy and the moisture of our clouded atmosphere clothes our fields with a lasting verdure unknown to the more favoured regions of Southern Europe. (7)

2439. *The deterioration of the British climate* is an idea entertained by some but whether in regard to general regularity, temperature, moisture, or wind, the alleged changes are unsupported by satisfactory proofs. It is not improbable but the humidity of our climate, as Williams alleges (*Climate of Britain*, &c 1816), has of late years been increased by the increase of evaporating surface, produced by the multiplicity of hedges and plantations; a surface covered with leaves being found to evaporate considerably more than a naked surface. If the humidity of the climate were greater before the drainage of morasses and the eradication of forests for agricultural purposes, a comparative return to the same state by artificial planting and irrigation, must have a tendency to produce the same results. However it will be long before the irrigation of lands is carried to such a degree as to produce the insalubrious effects of undrained morasses and as to our woods and hedges, we must console ourselves with the beauty and the shelter which they produce, for the increase of vapour supposed to proceed from them.

## BOOK IV

### OF THE MECHANICAL AGENTS EMPLOYED IN AGRICULTURE.

2440. HAVING taken a view of the vegetable and animal kingdoms, as supplying the subjects of agricultural improvement, and of the mineral kingdom, manures, and the weather, as the natural agents of their growth and culture our next course is to examine the mechanical agents, or *implements, machines, and buildings employed in agricultural operations*. In a rude state of husbandry few implements are required besides the plough and the cart, and few buildings besides the stable and the barn. The ground is ploughed and the seed thrown in and covered with a bush at harvest it is cut down and carted to the barn and the three grand operations of the farmer are sowing reaping and threshing but in our improved state of society, where all the science of mechanics as well as of chemistry is made to bear on agriculture, the implements, machines, and buildings become numerous, and equally so the operations. So numerous are the former, indeed, that the theoretical enquirer is often puzzled in making a selection. The whole of the most improved agriculture, however, may be, and in fact is, carried on with a very limited variety both of implements and buildings. Intricate and complicated machines are not adapted for a rustic art like agriculture, and a great variety are not required for one, the operations of which are so simple as almost to be universally understood and practised. In our enumeration we shall include a number that we do not consider of much consequence but we shall always distinguish between the essential and such as are comparatively objects of superfluous ingenuity and expense. We shall adopt the order of *Implements of Manual Labour, Implements or Machines impelled by Quadrupeds or other Powers, Structures, and Buildings*. We shall give a considerable variety, not altogether on account of their individual excellence, but to assist the mechanical reader in inventing for himself.

## CHAP. I.

*Of the Implements of Manual Labour used in Agriculture.*

2441 Though the most important implements of agriculture are drawn or put in action by beasts of labour, yet a few, which cannot be dispensed with, are used by men alone. These may be arranged as tools, or simple implements for performing operations on the soil; instruments for performing operations on plants or animals, or for other more delicate operations, utensils for the transportation of materials, and hand machines for various purposes.

SECT. I. *Tools used in Agriculture*

2442. *The lever* is an inflexible straight bar of iron or wood, employed in connection with a prop or fulcrum, on which it is supported. There are three kinds, but the most common is that in which the fulcrum is between the power and the weight. Its use in the removal of large stones or other heavy bodies is well known, and the advantage of its application depends on the distance of the power from the fulcrum, and the proximity of the weight.

2443 *The pick or mattock* consists of two parts the handle, which ought to be formed of sound ash timber or oak, such as is obtained from the root or butt end of a middle-aged tree, and the head, which should be formed of the best iron and pointed with steel. The handle ought to be perfectly cylindrical, as in using it one hand slides along it from the end next the operator towards the head. There are several varieties the first the pick, with the ends of the head pointed, used for loosening hard ground, gravel, &c.; the second, the pick axe, with the ends wedge-shaped in reverse positions, used in digging up trees the third, the grubber for grubbing up heath or small brushwood and there are also the road pick, and some others.

2444. *The spade* consists of two parts, the handle of ash generally about two feet nine inches long, and the blade of plate iron. The blade consists of two parts, the plate which cuts and carries the soil, and the tread, which is a piece of strong iron fixed on the upper edge of the blade, to receive the impulse of the foot of the operator. There are several varieties 1 with a curved outline to the extremity of the blade by which it may be made to enter a stiff soil with less exertion on the part of the digger 2 with a perforated blade which in adhesive soils frees itself better from earth in the using 3. with a sub-semicylindrical blade, which enters a stiff soil easier than the common form, is much stronger as a lever and also frees itself well from the spful of earth; this variety is what canal diggers chiefly use, and is called by them a grafting tool. There are other varieties and subvarieties used in draining, and for particular purposes which will be noticed at the proper place. Kitwell's spades, from the manner in which they are manufactured, for which Mr. E. has a patent, are said to be much stronger than any others.

2445. *The Flemish spade* (fig. 310) has a long handle, in some cases 6 or 8 feet, but no tread for the foot of the operator. The long handle forming a very powerful lever, when the soil is easily penetrated it may be dug with greater ease with this spade than with any of the forms in common use, and carts may be

310

filled with earth and earth thrown to a greater distance by this implement for the same reason. Add to this, that in no manner of using the Flemish spade, is the operator required to stoop as much as with the English one. (*Gard. Mag* vol. 14.)

2446. *The shovel* differs from the spade in being made with a broader and thinner blade its use being to lift, rather than to cut and separate. There are several varieties, differing in the form and magnitude of the blade. One variety, the barn shovel, has the blade generally of wood, sometimes edged with iron.

2447. *The turf-spade* consists of a cordate or scutiform blade, joined to a handle by a knee or bent iron shank. It is used for cutting turf from pastures, and in removing ant-hills and other inequalities. A thin section is first removed, then the protuberance of earth is taken out and the section replaced, which, cut thin, and especially on the edges, readily refits and the operation is finished with gentle pressure by the foot, back of the spade, or roller. One variety, (fig. 311) has one edge turned up, and is preferable where the turfs are to be cut square-edged and somewhat thick.

311

2448. *The fork* is of several kinds the dung-fork for working in littery dung, consisting of a handle like that of the shovel, and three or more prongs instead of a blade; the hay or pitch-fork, for working with sheaves of corn or straw or hay, consisting of a

B b

long handle and two prongs; and the wooden fork, consisting of a shoot of willow, ash, or other young tree or sapling, forked at the extremity, barked and formed into a rude fork, sometimes used in hay-making and similar operations. The prongs of forks to take up loose materials should be made square; those for sheaves or more compact matters or very heavy stuff will work easiest when the prongs are round.

2449. The rake used in agriculture is of two kinds, the hay-rake and the corn-rake. Both consist of a handle and head set with teeth in the corn-rake these are generally of iron. The garden-rake is sometimes used for covering small seeds.

2450. The hay-rake is usually made of willow, that it may be light and easy to work, and the teeth should be short, otherwise they are apt to pull up the stubble or roots of the grass in raking. Sometimes the teeth are made to screw into the head, and fasten with nuts, which prevents their dropping out in dry seasons.

2451. The corn-rake (Fig. 212.) is of different dimensions and constructions in different countries. In general the length of the rake is about four feet and the teeth of iron about four inches long, and set from one to two inches apart. Young (*Report of Norfolk*) mentions one of these dimensions which had two wheels of nine inches' diameter for the purpose of rendering it easier to draw the wheels were so fixed that the teeth might be kept in any posture at the will of the holder. It was used both for hay and corn, and answered the purpose well.

2452. In East Lothian a corn-rake has been tried, which, according to Somerville (*Sherry &c.*), has been found to answer much better than the common corn-rake. In this, the length of the head is from ten to fifteen feet, and the handle about seven feet, with a piece of wood across the end of it, by which it is drawn by two men. The teeth are of wood or iron; the last are the best, as well as the most durable, and are a little bent forward at the point, which gives them the power of reaching and carrying the ears along with them much better than they would otherwise do. To make clean work especially if the ridges are rounded, the field is raked across, in that way every thing is taken up but when it is preferred to draw the rake in the direction of the ridges, it may be considerably improved by cutting the head into two or three lengths (Fig. 213), and joining them with hinges, which will allow it to bend and accommodate itself to the curvature of the ridges. The advantage of this kind of rake has been found considerable, even in cases where every possible attention has been paid to the cutting of the crop.

2453. The stubble, or dew, rake, is merely a coarser sort of corn rake.

2454. The dewy-rake (Fig. 214) has teeth sharpened on both edges like lancets, and is used for raking or tearing off the flower heads or buds of daisies and other plants in grass lawns.

2455. The drill rake is a large-headed rake, in which the teeth are triangular in section, like small coulters and they are set at six or twelve inches' distance, according to circumstances. The implement is used to draw drills across beds or ridges, for sowing field crops of small seeds or roots, such as onions, early turnips, carrots, &c., or for planting saffron or Indian corn.

2456. The dung-drag, or dung-hack, is a two or three-pronged implement, with a long handle, for drawing the dung out of carts in different portions. The form of the prongs should be flat.

2457. The earth-hack resembles a large hoe, and is used for emptying loads of earth or lime, or other pulverulent matters, in the same manner as the dung-drag is used for emptying dung; it is sometimes also used as a hoe, and for scraping and clearing.

2458. The hand-hoe commonly used in agriculture is of two kinds: that with an entire, and that with a perforated, blade. The latter variety is preferable for thinning crops or destroying weeds, as it does not collect the soil and the weeds together in heaps; but where earthing up is the object, the common square blade is the best. The breadth of the blade may vary from two to twelve inches, according to the adhesiveness or looseness of the soil, or the distance to which the plants are to be thinned. An improvement for hoes to be used in stirring stiff soils, consists in forming the blade with a prong or prongs on the opposite side of the broad blade (Fig. 216), which can be used in very stiff places to loosen the earth, by the operator's merely altering the position of the handle. The blades of all hoes enter the soil easier when curved than when straight, the wedge in the former case being narrower.

2459. Various improvements in hoes have been attempted by agriculturists. One with a triangular blade

has been recommended as adapted to thin either at a greater or less distance, according to the depth it is thrust into the soil. Lord Stourville recommends the forked tool (fig. 215 a.) or heavy hoe, used in the vineyards on the Continent; but it is an implement more oppressive to the subsoil than a spade, as it requires him to stoop very low. Thunberg, jun. recommends a triple hoe (b) for thinning; another of a different description (c) for making drills by drawing one for making them by striking in a line, in order to form a trench for dung and potatoes (d); one for stirring a drill in the common way (e) and, lastly, one for hoeing both sides of a drill at once (f). It is said that by this last tool two acres of barley may be hoed in a day, and that it makes good work among oats or wheat; but such hoeing, even on the slightest soil, can be little more than a mere scraping of the surface; and though the weeds may be cut, yet this is only one object of hoeing.

217 The Dutch hoe is more frequently used in gardening than in agriculture; but, as it may sometimes be found preferable to the spade or dew-hoe, in cutting the weeds at the roots of young hedges and trees where it is not desirable to stir the soil more than an inch deep, we shall introduce a figure of the most improved form (fig. 217)

218 The thrust hoe (fig. 218) is an improvement on the Dutch hoe (Gard. Mag vol. i. p. 543)

219 The Spanish hoe (fig. 219) may be usefully employed on some occasions in stirring the soil among potatoes, where roots and weeds are abundant. To render stooping unnecessary, it should have a long handle. (Gard. Mag vol. ii. p. 65)

2463. The hoe-fork may be used as the Spanish hoe, and is most valuable where the roots of couch-grass abound. (Gard. Mag vol. ii.)

2464 The scraper may be described as a broad hoe, of treble the usual size and strength, used in cleaning roads or court-yards, and sometimes in cleaning grassy surfaces. One with the ends of the blade turned inwards an inch or two is found more effective in scraping the mud or dust from roads.

2465 Of weeding-tools used in agriculture there are three or four kinds one with a long handle and fulcrum to the blade, for digging docks and other tap-rooted plants from pastures; a common spud or spadelet for cutting smaller weeds in hedges or standing corn; a thistle-spud for cutting and rooting out thistles in pastures besides short-handled weaders of different kinds, to be used in hand-weeding young and delicate broad cast crops, as onions, &c. in stiff soils.

2466 Baker's thistle extirpator (fig. 220.) is an effective implement where that weed

abounds. It consists of a handle about four feet six inches long (a) claws between which the thistle is received (b), a fulcrum over which the purchase is obtained for extracting the root (c), and an iron rod or bar upon which the foot is placed to thrust the claws into the ground (d). In case the root of the thistle breaks while the operator is endeavouring to extract it, there is a curved blade, which has a sharp end like a chisel (e), which is thrust into the ground, in order to cut off the underground stem, some inches below the surface, and thus prevent or retard the re-appearance of the weed.

2467 Weeding-pincers, or thistle-drawers (fig. 221 a, b) are sometimes used for pulling thistles out of hedges and from among standing corn: the handles are about two feet six inches long, and the blades faced with plate iron made rough by cross channels or indentations. There is a variety of this implement called the Havre pincers (b) which is used in France both for pulling thistles and other weeds, and for taking tanch and oels from the ponds. (Thouss.)

2468 The besoms used in farming are commonly small faggots with handles, formed of barch spray for the stables and cattle-houses, and of broom, heath, straw, &c. for the barns.

2469 The straw-rope-twister, or twisting-crook (fig. 222.) is used for twisting straw ropes, and consists of a stick or rod from two to three feet long, and from one inch to

two inches in diameter, either naturally or artificially crooked. At one end is a ring, through which a cord is passed, and the implement tied to the waist at the other is a notch, on which the commencement of the rope is made. An improved tool of this sort (fig. 223,) is now used by the best farmers, it is held under the left arm, and turned with the right hand.

2470. The potato-dibber is exclusively used in planting potatoes in fine moulds but drilling is a mode generally to be preferred, as providing a better bed and a closer covering to the sets.

2471. The common dibber used in agriculture has several teeth or dibbles proceeding from a head, which, having a handle, is pressed into the ground, and forms several holes at once, according to the number of dibbles, and these are regulated by the hardness of the soil. In strong clays the common garden dibber, shod with iron is often used.

2472. The double-dibber (fig. 224) is chiefly used in Norfolk and Suffolk, for dibbling wheat but the more enlightened agriculturists of the present day consider that the pressing plough effects the same object, that of making a firm bed for the seed, more effectually and at less expense.

2473. Coggins's dibbling machine consists of a box fixed on wheels, to which are attached two conical dibbling irons, and the whole is to be moved forward by the foot of the operator (Newton's Journal, vol. ii. p. 88.) It appears to us much too intricate ever to come into use nor do we see the necessity of dibbling by manual labour at all, since we have the pressing plough, which is allowed to be preferable for wheat, and various drill machines, which are at least as good as the hand dibble, for beans.

2474. The flail is a well known implement for beating out corn now happily going out of use in the most improved districts, as it would go every where, were the value of the hand-threshing machine generally known.

2475. The essential agricultural tools are the pick, spade, shovel, dung and hay-fork, hay-rake, common hand-hoe, rope-twister, and besom.

## SECT. II. Instruments.

2476. The instruments used in agriculture may be classed as the executive and the scientific the former are used in executing, the latter chiefly in designing and laying out, operations.

### SECT. I. Instruments of Labour

2477. The instruments of labour peculiar to agriculture are few and chiefly the scythe, reaping-hook, and hay-knife but there are some others common to agriculture and gardening, which are occasionally used, and they also shall be enumerated.

2478. The scythe is of three kinds: one for cutting grass or herbage crops for hay which consists of a thin steel blade attached at right angles to a handle of six or eight feet long the second for cutting corn, to which what is called a cradle is attached the third is of smaller dimensions, and is exclusively used for cutting corn it is called the Halmak scythe.

2479. The Halmak scythe (fig. 225.) has a wooden handle an inch and a quarter in diameter and is held in the mower's right hand by the bent part (a, b) about five inches long. The straight part of the handle (c) is from 16 to 22 inches long, according to the height of the mower. There is a leathern loop (d) through which the fore finger is passed, and there is a knob (e) at the extremity, which would prevent the hand slipping off, if the loop should break, or the finger slip out of it. The blade (f) is about 2 feet long and 3½ inches broad at the middle. The handle is attached to the blade in such a manner as that its plane makes an angle with that of the latter by which means the mower is able to cut a little upwards, but almost close to the ground, without stooping, while the handle inclines to the horizon about 30 or 70 degrees. The line of the curved part of the handle (a, b) if produced, would nearly pass through the point of the blade, which thus gives the means of controlling that point whilst the fore finger in the loop commands the heel (e). Along with the scythe a light staff (g, g'), terminating in an iron hook (h), is used by the mower. With the scythe in his right hand, he holds the hook in his left by the middle, the curved part of it over the scythe in a similar position to the blade, and above it, their points being exactly over each other. In working, the mower moves both together, making the hook to pass behind the straw at about the middle of its height, to separate and draw it slightly down towards the left hand, while the blade follows with a motion from right to left, to cut off the straw at from two to four inches above the ground. A great advantage of this implement is, that the operator is not required to stoop, by which his strength is less exhausted, and he is able to cut double the quantity of corn which can be cut in the same time with the reaping-hook, and with less loss of straw. Two Highland Society of Scotland trials, extraordinary evidence to favour this instrument being the success of that society in 1825, and through the assistance of the Chevalier Macdonald, then the French consul at Edinburgh, and two young farmers, brought over by the Highland Society which accompanied this excellent man in a tour through the country it occasioned in making a great many trials. The general result, as communicated in the

Society's Report of December 1825, is, that by the use of this instrument, as compared with the sickle, in the cutting of wheat, there is a saving, at an average of the different statements given, of 58 per cent. Notwithstanding this circumstance, however, the Harmscut scythe has been very little used since in Scotland, partly, no doubt, owing to the difficulty of overcoming established prejudices—partly, also, because any workman whose frame has been accustomed to use an description of instrument, must begin by undergoing a good deal of bodily suffering and loss of labour before he can so far master another so very different as the Harmscut scythe is from the sickle, as to do the same

quantity of work with the one as with the other—but principally we suspect, because the instrument has, if any, no great advantage over the scythe hook. Young persons alone are to be expected to learn the use of difficult instruments, and bring them finally into general reputation. The editor of the Highland Society's *Transactions* in speaking of this Report (vol. vii. p. 520), says that, considering its favourable nature, "a somewhat different result might have been anticipated than has really occurred. But, although three years have elapsed since these experiments with the Harmscut scythe were made, the instrument itself has nowhere come into general use. That it is an important and useful mode of reaping cannot be reasonably disputed; but we ought not, perhaps, to anticipate any important change in harvest-work until that great era (we hope not very remote) when the acquisition of a horse-machure, applicable to all ordinary circumstances, shall secure our crops, and sweep every prejudice before it. Still, as there will always be small farmers and cottagers who cannot afford to have reaping machines, we think it highly desirable that the Harmscut scythe should have further trials, and we earnestly recommend it to our friends in America and Australia."

2480 *The cradle-scythe* is variously constructed sometimes the cradle or receptacle into which the corn is gathered is of network (fig. 226), and at other times it consists of woven laths or wicker work. (See § 405)

2481 *The reaping-hook* is a curved blade of steel fixed in a short wooden handle—it is of two kinds—one serrated like a fine saw which is used in cutting corn by handfuls, and is called a

sickle hook—the other smooth and sharp like a scythe, which is used to hack the corn over in the peculiar manner called bagging, and is called a cutting hook. The most improved form (fig. 227) has a kneed handle.

2482 *The smooth reaping-hook*, or as it is called in East Lothian, the scythe-hook was first introduced into the West and South-west of Scotland, probably from Ireland, and has now spread over most of the Lowlands. It is considered much preferable to the common reaping-hook in our best corn counties. (See *Farm Mag.* vol. xxi. p. 55) Where the crop is very thin and short, it requires some attention to make clean work, and in such cases the toothed hook, or Hutton's improved reaping-hook, may do it better—but upon all ordinary good and strong crops, the scythe hook is by far the better implement, the reaper with equal ease to himself cutting down a third or fourth more than with the old toothed hook. The impression of some of the best Scotch farmers is, that a labourer will do as much work with it as with the Harmscut scythe, and cut the straw almost if not altogether as close to the ground.

2483 *Hutton's improved reaping-hook* is serrated from the point through half its length like a sickle, and the remainder smooth and sharp. The advantage is, that the straw is not cut in entering the hook as in the case where the point is of the cutting kind, by which means fewer drops and are lost. With sickles rapiers invariably make cleaner work than with the hooks for the above reason—with hooks the straws are cut with less labour. (*Trans. Soc. Arts* vol. xxviii.)

2484 *The hay-knife* consists of a straight blade, set at right angles to a short wooden handle both of considerable strength. It is used for cutting hay or straw when consolidated in the rick or stack. An improvement of this instrument has been proposed, which consists in forming the blade like that of a common spade, sharp at the edges, by which the operator will cut downwards instead of obliquely and not being obliged to stoop, will effect the same work with far less trouble.

2485 *The wool-shears* are formed wholly of iron or steel, and worked with one hand.

2486 *The hedge-shears* are of different kinds, that called the *averruncator* is to be preferred for cutting off large shoots, as it makes a clean draw-cut like a knife. Shears, however, are not used in dressing hedges by the best agriculturists.

2487 *The thatching-knife* consists of a blade similar to that of a scythe, inserted in a wooden handle like that of a reaping-hook. For thatching with reeds, heath, or any rough and rigid thatch, the blade has a handle affixed to each end to enable the operator to work it with both hands.

2488. *The stack-borer* consists of two parts, a cutting screw or blade (fig. 228 a), and a drawing screw (b). Both are worked by cross handles in the usual manner (c). In using this instrument, which is of great importance where hay has acquired a dangerous degree of heat, first cut away the loose hay where the borer is intended to be applied, then insert the point of the borer and by means of the cross handle turn it round till the stack is pierced—either

quite through, or to a sufficient depth, then withdraw the cutter, and, by means of the

drawing screw repeatedly applied, take out the plug of hay which has been detached. If, however, the hay be in a moist, heating state, it will occasionally coil round the cutter in proportion as it is pierced, and impede its action. In such cases, the drawing screw must be slipped over the rod of the cutter, and must be applied from time to time, to draw out the hay, in proportion as it is detached from the mass. (*Newton's Journal*, vol. v. p. 306.)

\*2489. The hedges are of various kinds. The schmiter (*fig. 229. a*) has a handle four

229

feet long, bent a little out of the direction of the blade in order to admit the free action of the operator's arm while standing by the side of a hedge and cutting upwards. The axe (*b*) is used for cutting strong boughs or small trees, the bill-hook (*c*) for fagoting, and stopping gaps in hedges; the dress-hook (*d*) for cutting the twigs in very young hedges, and for dressing faggots and the bill-hook (*e*) for lopping branches close at hand. A chisel with a handle eight or ten feet long is used for cutting off branches eighteen or twenty feet from the operator and is of considerable use in pruning forest trees in plantations or hedges, and also fruit trees in orchards.

230

\*2490. The axe, saw, wedges and hammers, of different kinds and sizes, are used in agriculture, in felling trees, cutting them up, preparing fuel, driving nails, &c. but these and other instruments common to various arts need not be described.

\*2491. The scower (*fig. 230.*) is a well known instrument used by woodmen in marking numbers on timber trees.

\*2492. The line and reel is occasionally wanted for the manual operations of agriculture, and should be procured rather stronger and with a longer line than those used in gardens.

\*2493. The potato set scoop is of two kinds; one a hollow semiglobe, (*fig. 231. a*), and the other (*b*) a section of that figure. They are only used when potatoes are very scarce, as in ordinary cases the larger the set the more strength and rapidity of growth in the young plant.

231

\*2494. The Edinburgh potato-scoop (*fig. 232.*) is by far the best, and indeed the only one deserving of use. The handle (*a*) has a round stem which passes through a piece of metal (*b*) and has there a semicircular knife or cutter (*c*) fixed to it. This cutter is sharp on both edges, and turns on a pivot fitted in a piece of brass turned out of a piece of plate (*d, e*). This plate forms a shield to hold the instrument firm upon the potato, by placing the thumb of the left hand upon it, and pressing the point in which the cutter is fixed into the tuber. Then by turning the handle round with the right hand, the semicircular knife cuts out a set, which is a segment of a small sphere (*f, g*). The only attention necessary in the use of this instrument is, to place it upon the potato, with the eye or bud in the centre of the diameter of the semicircle of the knife when laid flat on the tuber. The advantages of this scoop, besides that it is very quick in its operation, is that the pieces being all exactly of one size, that is about six inch in diameter, may be planted by a beam-barrow or drill machine, with much less labour and more accuracy than by the hand.

232

half round with the right hand, the semicircular knife cuts out a set, which is a segment of a small sphere (*f, g*). The only attention necessary in the use of this instrument is, to place it upon the potato, with the eye or bud in the centre of the diameter of the semicircle of the knife when laid flat on the tuber. The advantages of this scoop, besides that it is very quick in its operation, is that the pieces being all exactly of one size, that is about six inch in diameter, may be planted by a beam-barrow or drill machine, with much less labour and more accuracy than by the hand.

\*2495. The essential instruments of labour are the scythe, rumping-hook, hay-knife, wool-shears, hedge-bill, axe, saw, hammer, and line and reel.

SECTION. 2. *Instruments of Science.*

2496. *Scientific instruments* are not much required in agriculture, the principal are for levelling, boring, and measuring.

2497. *The level* is frequently required in agriculture, for arranging surfaces for irrigation, tracing strata in order to cut off springs, well-making, and a variety of other purposes. The simplest form is the common road or mason's level, and the most complete the spirit level, with a telescope and compass, such as is used by land-surveyors but when operations of only moderate extent are to be performed, very convenient and economical substitutes, and if used with care, equally accurate instruments, may be found in Parker's level, the road or common level, water level, the triangular and the square level.

2498. *Parker's level* (fig. 233.) consists of two cylindrical receivers of about five eighths of an inch in interior diameter and full three inches high each, for holding quicksilver, fixed at right angles upon a wooden stand, and about eighteen inches asunder. A small groove is cut lengthwise in the stand, and closely covered over, through which channel a communication is effected between the two cylinders and consequently the surfaces of the quicksilver in the cylinders must be on a level with each other. The two floats are equal to each other as to weight and length, and the surfaces (about five eighths of an inch in diameter) which rest on the quicksilver in each cylinder; and consequently the tops of the floats must also be on a level with each other. The different parts of the level are closely fitted, and the whole rendered portable by screwing up the floats into the caps of their respective cylinders. About three minute grooves are cut in the lower, or hemispherical ends of the floats, through which the quicksilver rises upon a slight pressure of the floats, and falls back again under the floats as soon as the pressure is taken off. The tops of the cylinders are a little concave, for saving any particles of quicksilver which may lodge in the screws, when the instrument has been shaken in the carriage. Constructed and sold by Mr. Appleton of Drury Lane, London, turner price 14s. each; staff with cords and pulleys, 8s. and three legs five feet high, 4s.

and for the purposes of road-making and irrigation it is furnished with plates of iron with adjusting screws, for the purpose of determining the slopes of surfaces.

2500. *The water-level* is that which shows the horizontal line by means of a surface of water or other fluid founded on this principle, that water always places itself level or horizontal. The most simple level of this kind is made of a long wooden trough or canal, which being equally filled with water, its surface shows the line of level. It is also made with two cups, fitted to the two ends of a straight tube, about an inch in diameter, and three or four feet long, by means of which the water communicates from the one cup to the other, and this pipe being movable on its stand by means of a ball and socket, when the two cups shew equally full of water, their two surfaces mark the line of level. It may also be made with two short cylinders of glass, three or four inches long, fastened at each extremity of the pipe with wax or mastic. The pipe is filled with common or coloured water, which shows itself through the cylinders, by means of which the line of level is determined, the height of the water with respect to the centre of the earth being always the same in both cylinders. This level is very simple and commodious for levelling small distances.

2501. *The American or triangular level* (fig. 235 a) is formed of two pieces of this wood joined by a cross bar, the whole in the form of the letter A. The manner of using it is simply this: At the place from which the level is to be taken, drive a wooden peg into the ground, close in to the top, upon which one of the legs of the frame or A may rest, then bringing round the other leg till it touch the ground, there drive in a second peg, turning round the other leg as before, and where it touches the ground again, drive in a third peg, and so on along the whole line to be levelled. Thus, with very little trouble, and with as much accuracy as with the finest spirit-level, may the centre of a drain be easily ascertained. But as it is necessary that a drain should have sufficient declivity to allow the water to run freely it will be requisite, in taking the level,

to regulate the direction of the line accordingly. Half an inch fall, in the length of the frame, will be sufficient. For this purpose, it will be expedient to have, besides a number of wooden pegs, one iron pin with a hook, and others marked regularly upon the sides of it from the top downwards. After having driven in the first wooden peg at the point whence you mean to conduct the drain, and having riveted the one leg of the frame upon it, turn round the other till it be level with the first peg; there put in the iron pin, so that this leg of the frame may rest on the top of it, when level; then drive in a wooden peg as far as that the top of it may be half an inch lower than that of the iron pin. Place the leg of the frame again upon this second peg, turn it round to a level, putting in the iron pin all the top of it be equal with the foot of the frame. Then drive in another wooden peg close by the side of it, till the top of the wooden one be half an inch lower than that of the iron pin. Proceed in this manner as far as you mean to carry the drain, which will have the same degree of declivity all the way along. When made on a smaller scale, it is useful in ascertaining the proper descent along the bottom of a drain, while the workmen are laying it; but when made for this purpose, the cross-bar must be fixed to the bottom of the legs, so that the A becomes a B, or delta.

2502. The *square level* (fig. 255 b), is made of several pieces; the usual length generally five feet and a half, and the height four feet, or four feet and a half. It may be either used like the water level, or the American level. According to Marshal, it has been found "preferable to any level now in use, as being equally accurate in ascertaining the relative heights of distant objects, as in minutely tracing step by step the required line of communication, so as to give every part of it an equal and uniform descent.

2503. The *object staff* (fig. 255. c) is used with the water or square level for either it should be exactly of the same height as the level; the cross piece at top should be a foot or more in length, and three inches broad, painted white on one side for opposing to dark objects, and black on the other for opposing to such as are white.

2504. The *levelling staff* is composed of two pieces (fig. 255. d, h, and e, c), which slide on each other: they are each of about five feet in length, so as to form, when fully extended, a rod of ten feet. They have a line of feet graduated into hundredth parts. The index (f) slides firmly on them and is moved up or down (by signal) by the attendant who carries the staff, till the observer finds it coincide with the intersecting wires of his telescope. Its height on the staff, of course, marks the difference of the level. It has two horizontal and parallel black stripes, which at considerable distances are of use to direct the eye more readily to the fiducial edge (g).

2505. The *measuring-chain, measuring-rod, pocket-rule, poles* for setting out straight lines, stakes for driving in at fixed points, and a variety of other instruments, and their appendages, are occasionally required by the agriculturist who lays out estates, or effects territorial improvements: but these, not being strictly agricultural implements, do not require to be described.

2506. The *odometer* (odre, a way and metre, to measure) is a very ingenious instrument, invented in 1821 by Mr Hunter of Thurston in Scotland, who has given the following description of it to the Highland Society. The wheel *a* (fig. 256) is made of light iron, and measures two yards in circumference, being divided by six spokes into feet. One spoke must be painted white. The handle is divided at *c*, like a fork, and contains each end of the axle by its elasticity. Through the axle is a hole into which the end *d* of the way-wear fits, and is held fast by a nut *e*. The way-wear (fig. 257) consists of a frame *f* g being hollow to receive a perpetual screw *h*, a part of which is visible near the index *u*. At the other end of the screw is a nut *v*, which keeps it in its place. The screw turns two brass concentric cogged wheels *k* and *l*. *k* conceals the scale of *l*, except where a piece is cut out, leaving an index at the beginning of the scale of *k*, and which in the dialing points to 75 of *l*. The scale of *l* is numbered towards the left, and that of *k* to the right. The wheel *k* has 100 teeth or turns, and *l* 101 consequently as the same endless screw turns both wheels, it is evident, that when *k* has made a complete revolution of 100 teeth, *l* will also have made a revolution of 100 teeth, and the index of *k* will point to 1 of *l*; however *l* has 101 teeth. After a second revolution it will point to 2, and so on: the number it points to marking the number of revolutions; each revolution showing 100 turns of the iron wheel *a*. Accordingly, *a* measures 6 feet, or 1 turn; *k* 100 times 6 feet, or 600 feet, or 1 revolution; and *l* 101 times 600 feet, or 60,600 feet, equal to nearly 11½ English miles, the range of the instrument. 88 turns of this wheel make a mile. It is advisable always to commence with the way-wear set at 0 or zero: to do this, take out the screw in the centre, when the brass wheels *k* and *l* can both be set at zero, and the screw replaced. Put the wheel *a* upon the ground with the white spoke underneath, and fix the way-wear into the wheel by means of the nut *e*, always observing to put it on the left side, as shown in the plate *at c*. At any period of measuring you can tell exactly how far you have gone, and proceed without again setting the way-wear at 0. Suppose, as in the figure, the spoke No. 2 at the ground, the index *u* pointing at 35 of *k*, and the index of *k* pointing at 75 of *l*; then the distance measured is 7500 turns of *a* and two feet, and as *a* measures two yards, 7500 x 2 = 15100 yards, to which add the two feet. In reading off, particular care must be taken always to read the large figures (viz. those on the wheel *l*) first, and afterwards to add the small figures (viz. those on the wheel *k*); and, if the figures on *k* amount to

less than 10, a 0 must be prefixed, so that  $k$  shall always show two figures; for instance,  $k$  being at 45 and  $h$  at 4, the sum is 494. The correct way to guard against error is to read 45 and add the word *hundred*.

237

dred thus, forty-six hundred and four and not four thousand six hundred and four. It is hardly necessary to point out the advantage of having such an instrument. No country gentleman who takes the smallest charge of his own affairs, should be without one, as, by merely walking from one end to the other of any road, hedge, wall, ditch, &c. with the odometer (which is not more troublesome than a walking stick) he can tell the length of it much more correctly than by a measuring chain, which, to say the least of it, requires two honest men, one at each end, and who must be both paid for their trouble, whereas the gentleman himself, whose honesty cannot be doubted as he is not likely to cheat himself, can at no expense, measure with this instrument at least four times as quickly as those with the chain, who have it also in their power to mismeasure, if I may use the expression, six inches every time a peg is put into the ground but its principal uses are to check measurements already made, and to measure off the use of any proposed improvements, such as plantations, gardens, &c. (*Trans H Soc* vol. vi p 603)

2507 *Good & improved instruments for boring the earth for water, draining, and other purposes, may now be considered as having superseded all others, and we shall shortly describe them.*

2508. *The auger (fig 238 a) is to be connected by the screw-head to the length of rods by which the boring is carried on. This auger is for boring in soft clay or sand, it is cylindrical and has a slit or opening from end to end and a bit or cutting-piece at bottom. When the earth is loose, or wet, an auger of the same form is to be employed, but with the slit or opening reduced in width or even without a slit or opening. A similar auger is used for cutting through chalk but the point or bit at bottom should then project lower and for that purpose some of these cylindrical augers are made with moveable bits, to be attached by screws, which is extremely desirable in grading them to cutting edges.*

2509. *The hollow conical auger (b) for boring loose sandy soils, has a spiral cutting edge coiled round it, which as it turns, causes the loose soil to ascend up the inclined plane and deposit itself in the hollow within.*

2510. *The hollow cylinder or tube (c) with a foot valve, and a bucket to be raised by a rod or cord attached at top, is a pumping tool for the purpose of getting up water and sand that would not rise by the auger.*

When this cylinder is lowered to the bottom of the bore, the bucket is lifted up by the rod and cord and descends again by its own gravity having a valve in the bucket, opening upwards like other lift pumps, which at every stroke raises a quantity of water and sand in the cylinder equal to the stroke, the ascent and descent of the bucket being limited by a guide-piece at the top of the cylinder and two small notches upon the rod, which stop against the cross-guides.

2511. *The tool for getting up broken rods (d) consists of a rod with a small cylindrical piece at bottom, which the broken rod slips through when it is lowered and a small notch with a knife-edge, acted upon by a back-spring. In raising, the tool takes hold of the broken rod, and thereby enables the workman at top to draw it up.*

2512. *Another tool for the same purpose (fig 238 e) is like a pair of tongs it is intended to be slid down the bore, in order that the broken rod may pass between the two cutters, which, pressed by back springs, will, when drawn up, take fast hold of the broken rod.*

2513. *The tool for widening the hole (f) is to be connected, like all the others, to the end of the length of rods passed down the bore, this tool has two cutting pieces extending on the sides at bottom, by which as the tool is turned round in the bore, the earth is pulled away.*

2514. *The chisel or punch-stone (g) has a projecting piece to be used for penetrating through stone. This chisel is by rising and falling made to peck the stone and pulverise it, the small middle part breaking it away first, and afterwards the broad part coming into action. Another chisel, or punching-tool (h), is twisted on its cutting edge, and is used for breaking away a greater portion of the stone.*

2515. *A flying tool (i) is used when it happens that an auger breaks in the hole. On one side of this tool a curved piece is attached, for the purpose of a guide to conduct it past the cylindrical auger;*

239

end of the end of the other side is a hook, which taking hold of the bottom edge of the auger enables it to be drawn up.

2516. The triangular clew (fig. 240 *B*) is used when loose stones lie at the bottom of the hole, which are too large to be brought up by the cylindrical auger, and cannot be conveniently broken. The internal meshes of this instrument take hold of the stone, and as the hole rises it brings them up. For raising broken roots a tool (*B*) is sometimes employed, which has an angular clew that slips under the shoulder of the root, and holds it fast while drawing up. (*Newton's Journal*, vol. vii. p. 267.)

2517 Other tools connected with the subject of boring for water also invented by Mr Good, will be described when the operation of boring is treated of, in Part III. Book III. Chap. III. (See Contents.)

2518. *Bushy's borer for quicksand* (fig. 241) consists of a tube called a sludger, from five to six feet in length, made of plate iron, with a valve at its lower extremity, made partly of iron and partly of leather, which works upon an iron hinge, and a hole at the top (*a*) through which it is emptied.

In boring through quicksands a metal pipe is inserted into the borehole, and the sand is withdrawn from it by the sludger, which, by means of the valve at its lower end, acts as a pump. A second metal pipe is added to the first, and so on to any depth. (*Trans. High. Soc.* vol. vi. p. 611.)

2519. The *post-borer* (fig. 242) is a larger sort of borer, employed in peaty soils that are boggy for the purpose of removing wetness. It has been used with advantage in some post-moors in Lancashire, by Eccleston.

2520. The *blasting auger*, *slender measure* and other scientific instruments, not in general use in agriculture, will be best described in treating of the departments in which they are applied.

2521 The *only essential scientific instrument* is the common level, which may be wanted to level drains and water furrows, adjust the surface of roads, &c.

### SECT. III. Utensils used in Agriculture.

2522. The *principal agricultural utensils* are sieves, baskets, corn-measures, and sacks.

2523. *Sieves* are textures of basketwork, wire, gut, or hair, stretched on a broad wooden hoop. Sometimes, also, they are formed of skins or plate iron pierced with holes, and so stretched. They are used for separating corn, or other seed, from dust or other extraneous matters. There are different varieties for wheat, beans, oats, rape-seed, &c.

2524 The *corn-screen* (fig. 243.) consists of a hopper (*a*), with a sliding board (*b*) for giving more or less feed slips of wood (*c c*) fixed on pivots to prevent the grain from passing too quickly down and the screen, which is composed of parallel

wires (*d*).

2525. *Baskets* are made of wickerwork, of different shapes, but generally forming some section of a globe or figure: they vary much in size those in most general

use in agriculture are from twenty inches to two feet in diameter, and are used for carrying roots, chaff, cut straw &c., from one place to another in the farmery. A very good substitute for a basket for filling sacks (fig. 244.) formed of iron, is in use in Nottinghamshire, Lancashire, and other counties. (*Gard. Mag.* vol. v. p. 674.)

2526. The *seed-carrier or seed-basket* (fig. 245) is sometimes made of thin veneers of wood, bent into an irregular oval, with a hollow to fit the seedman's side, and a strap to pass over his head, and rest on his shoulder. In some places, a linen bag of a shape adapted to be borne by the right shoulder, and to suspend the seed under the left arm, is used for the same purpose.

2527 The *feeding tub or trough* may be of any shape and size, it is used for giving short or liquid food to swine, sheep, and other live stock.

2528. The *pail* is used for carrying water, or other liquid food.

2529. The *turnip tray* is a shallow movable trough or box, used to prevent waste when sheep are fed upon turnips.

2530. The *corn bin, or corn chest*, for containing oats or other grain for horses, may be an oblong box of any convenient size. Sometimes it is placed in the loft over the stable, and the corn is drawn out by a hopper below; but for a farm stable this is needless

trouble: there it is commonly placed in the broad passage behind the horses, or in any spare corner. It should be stout, and have good hinges, and a safe lock and key.

2551 *The flexible tube*, for relieving cattle that are hoven or choked, consists of a strong leathern tube about four feet long and about half an inch in diameter, with a leaden nozzle pierced with holes at the insertion end. It should be kept in every farmory. There is a similar one, on a smaller scale, for sheep, which should be kept by all shepherds. Both will be found figured and described in Part III Book VII.

2552 *Jones's grain-drying apparatus* (fig. 246. section) consists of two concentric cylinders about six feet in diameter and is from the bottom to the top of its cones twelve feet high. The outer cylinder may either be perforated with small holes, or made of wire gauze. In the centre of the inner cylinder are a fire-place and chimney. The grain to be dried is admitted between the cylinders through a hopper at top, and distributing itself round the internal cone, it is discharged through a spout into a sack or receiver. In passing the grain becomes heated, and the moisture evaporates, and passes off through the perforations of the exterior cylinder. (*Newton's Journal*, vol. vii p. 214.)

2553. *Corn measures* consist of the hippie, peck, and bushel, with the strike or rolling pin to pass over the surface, and determine their fulness. The local measures of every country are numerous: the imperial bushel is now the standard corn-measure of the three kingdoms.

2554 *Corn sack or bags* are strong hempen bags, calculated to hold four bushels, and in Scotland four triots.

2555 *Other utensils*, as those of the dairy, poultry, and cider-house, will be described in their appropriate places.

2556 *The essential agricultural utensils* are the move basket, seed-carrier tub, pail, corn chest, flexible tube, corn measure, and corn sack.

#### SECT. IV Hand Machines used in Agriculture.

2557 *Agricultural hand machines* are generally portable, some are exclusively put in action by man, as the wheel-barrow, and others, as the straw cutter, sometimes by horses, water or other powers.

moving earth or stones; the dung barrow (fig. 248.) for the farmyard and the corn barrow (fig. 249.) for conveying corn from the stackyard to the barn. The body of

2558. *The common ladder* is the simplest of manual machines, and is in constant use for forming and thatching ricks, and for other purposes, with or without the use of trestles and scaffolding.

2559. *The wheel-barrow* is of three kinds — the new ground work barrow (fig. 247) used in the farmyard and the corn barrow (fig. 249.) for conveying corn from the stackyard to the barn. The body of

the latter (b) may be made to separate from the frame and wheel, and by means of levers (a) to be carried like the hand-barrow.

2560. *Barrows for hay and straw* may be variously

constructed, and near towns (figs. 250, 251) may be used for wheeling light packages.

2561 *The sick-barrow* is a two-handed lever of the first kind, the fulcrum of which

is a pair of low wheels. It is a convenient machine for moving sacks in a granary or barn floor, from one point to another.

2542. The *Normandy wheel-barrow* (fig. 252) is said to be exceedingly useful on a farm. The handles or trams (a a) are nearly fifteen feet in length, by which, when loaded, nearly all the weight is thrown on the axle, so that the man has almost nothing to carry, and has only to push. He is thus saved from being bent down while at work, and consequently from acquiring a habit of stooping. A shoulder strap (b) is commonly used by the operator (*Morvi Pinck, and Gard. Mag. vol. vi*).

2543. The *truck* (fig. 253.) is a machine of the barrow kind for conveying compact heavy weights, such as stones, metals, &c.

2544. The *hand-barrow* is of different kinds (figs. 254, 255, 256) and is in frequent use in various departments of agriculture, where the soil is soft, or the surface uneven. Its bottom should be close and strong for carrying stones but may be light and open for dung or corn.

2545. The *winnering machine*, originally introduced from Holland to East Lothian by Mr James Meikle of Saltoun, father to Mr Andrew Meikle, the inventor of the

threshing machine (799.), is in use for cleaning corn in most of the improved districts. There are different forms, but the best are those founded on the Meikle or Berwickshire winnower, which, instead of one screen has a set of sieves put in motion by the machine, by which means the corn comes out, in most cases, ready to be meted up in sacks. A highly-improved form of this machine, and the most perfect, we believe, at present in use (fig. 257) is manufactured by Warr and Co. of London.

2546. The *hand threshing-machine* (fig. 258) is worked by two men and one woman, and is sometimes used for threshing the corn of a small farm, or for threshing clover or other small seeds. The advantage consists chiefly in the completeness in which the grain is separated from the straw, there is no saving of human labour, unless the power of horses or water is applied.

2547. The *potato cleaner* is a hollow or perforated cylinder or barrel, with a wooden axle through its long diameter, and a handle at one end, by which it is turned like a barrel churn. A hinged board forms an opening for putting in and taking out the potatoes, which fastens with an iron hasp and staple. It is filled one third with potatoes or other roots, and then placed in a cistern of water, by means of a crane or otherwise. In this state, being two thirds immersed in the water, and one third full of potatoes, it is turned round a few times, when the latter are found cleaned, and the barrel is lifted out by the crane, emptied, filled, and replaced.

2548. A *locomotive steam threshing-machine*, capable of propelling itself and a man, has been constructed in the county of Northumberland. It is intended for the small farmers, as it can be moved from one farm to another, and thus enable them to thresh

out their corn expeditiously and perfectly clean. The steam engine is not intended to be confined to threshing, as, by particular arrangements, it may be applied to the drawing of waggons, pumping of water, breaking of stones, &c.

2549. The *maize-sheller* (fig 259.) is composed of a thin vertical wheel covered with iron on one side, made rough by punctures, which wheel works in a trough, and separates the grains from the stalks by rubbing. The ears or spikes of corn are thrown in by hand one at a time and while the separated grains pass through a funnel below, the naked stalk is brought up at the end of the wheel opposite to that at which it was put in. The wheel may either be made rough on both sides, or on one side, according to the quantity of work required to be done, and the force to be applied.

2550. *Marutt's improved maize separator* (fig 260) is the most perfect machine of this kind at present in use. It has not hitherto been much used in England, but a good many have been exported to America and the colonies. A machine for the same purpose, by Cobbett, will be figured and described in Part III. Book VI.

2551. A *hand flour-mill* (fig 261), for grinding Indian corn, consists of one wheel and pinion, a fixed French burstone, and a similar stone in motion over it. The corn passes through a hopper in the usual manner, and comes out from the stones fit for the bolting machine. The hand flour-mill is chiefly used for Indian corn, but it will also grind wheat and other corns into meals of tolerable fineness. It requires two men to work it, and the price in London is from ten to sixteen guineas.

2552. A *hand bolting-machine* (fig 262.), consists of a half cylinder of wire with cross brushes (a), enclosed in a box (b) about four feet long by twenty inches on the sides. It may be considered a necessary appendage to the hand flour-mill, and costs in London from three to five guineas.

2553. The *bone-breaker* (fig. 263) is an ingenious and most useful machine where large bones are grown or found naturally. The bones are bruised and cut into short lengths by hammers which operate like those in the mills for hammering iron. When the material is not sufficiently bruised, it is afterwards passed between rollers.

263

2554. The *bone-trunking machine* (fig. 264.) consists of two rollers grooved and indented, and with pinions on their ends, by which they may be moved either by animals, water, or steam power. The surfaces of the rollers are fitted with indentations and strong teeth, which penetrate and break the bones to pieces. This is accomplished by employing separate cast-iron wheels placed side by side upon an axis, to compose the

264

similar to those of a saw or ratchet wheel each wheel of the lower roller is an inch thick, and they are placed at distances of an inch and a half asunder, having circles of hard wood or iron placed between them, which are two inches less in diameter. The bones should be supplied rather gradually to the machine at first, to avoid choking it, and the rollers should then be adjusted to a considerable distance asunder but when the bones have once passed through in this way, the rollers are screwed closer by screws placed for that purpose, and the fragments ground a second time. The pinions (a a) must have deep cogs to enable them to take deep hold of each other, when the rollers are set only half an inch distant to grind fine, and without the cogs being liable to slip when the centres are separated so far as to leave a space of one inch or one inch and a quarter between the rollers, for the passage of the large bones the first time. The rollers will act most

effectually, if the different wheels are fixed upon their axles in such a position that the teeth will not correspond or form lines parallel to the axes, and then no piece of bone can escape without being broken by some of the teeth. The bones which have passed through the rollers slide down an inclined board, and collect at the bottom in a

265

large heap. When all the stock of bones are thus coarsely broken, a labourer takes them up in a shovel and throws them again to the hopper to be ground a second time. (*Suppl. to Encyc. Brit. Art. Agr.*) In a modification of this machine to be impelled by horse power manufactured by Wier of London (fig. 266.), the bones, after passing through the rollers, are conducted by the hopper (a) into a revolving screen (b), which is driven by a bevel wheel (c) working into a pinion on the screen shaft (d, e).

2555. The *oil-cake breaker* is composed of two rollers ground and toothed like the rollers of the bone-mill, but it is on a smaller scale so as to be worked by one man. The object is to break the oil-cake to a dust or powder. Below the rollers is a screen for separating the grosser pieces which are set apart for feeding cattle, and

the finer material or dust is reserved for sheep or for manure. Price in London from 8 to 11 guineas.

2556. *A stone-breaking machine impelled by steam* may be constructed of two fluted rollers, placed side by side, about an inch apart, and turning different ways. The stones are put into a kind of hopper above, and pushed down with a rake, affording a regular supply to the roller. It is worked by one of Kay and Routledge's rotatory engines, of one-horse power, and will completely break a ton of hard pebbles in about six or eight minutes. (*Newton's Journal*, vol. vi. p. 158.)

2557. *The root-breaker or bruiser* (fig. 266) is composed of two widely fluted rollers, placed under a hopper, turned by two men. It is used for breaking or bruising potatoes, turneps, carrots, or other raw roots, into small or moderate sized pieces, before giving them to cattle or horses. The same implement may be set so close by means of two screws, as to serve for a whin-bruise, or for breaking beans or corn of any kind.

2558. *The corn-bruising machine* (fig. 267) is contrived for the purpose of bruising or kibbling different sorts of grain, pulse, &c. as well as grinding malt. It is a simple implement, constructed with two iron rollers of different diameters, turned true on their axes or spindles, each roller having a cog or tooth wheel. A roller with grooves is fixed under the hopper, to receive the grain from the hopper, and lay it on the two rollers. To one of the rollers is fixed a fly-wheel. The machine is made to be worked by hand, or any other power. The upper wood frame is made to slide, and is regulated by a screw, according to the use of the grain, and will bruise it more or less as may be required.

2559. *The potato flour-mill* (fig. 268.) consists of a cylinder (a) covered with tin-plates pierced with holes, so as to leave a rough surface, in the same manner as the graters used for nutmegs, &c., but the holes in this are larger. This cylinder is situated beneath a hopper (b), into which the potatoes are thrown, and thence admitted into a kind of trough (c), when they are forced against the cylinder, which, as it revolves, grinds the potatoes to a pulp. Motion is given to the machine by a handle fixed upon the end of the axis of the grating cylinder (a), and on the opposite extremity of this axis is a fly-wheel (d) to regulate and equalise the movement. The potatoes, when put into the hopper, press by their weight upon the top of the cylinder, and, as it revolves, they are in part grated away. On one side of the lower part of the hopper is an opening, closed or opened more or less, at pleasure, by a slider (e) and the degree of opening which this has, regulates the passage of the potatoes from the hopper into the trough (c). This is as wide as the length of the cylinder, and has a concave board (f) fitted into it,

which slides backwards and forwards by the action of levers (*g*), fixed to an axis extended across the frame of the machine; a lever (*h*) is fixed upon this axis, causing a weight which acts upon the beard (*f*) by means of the levers, to force or press forward the potatoes contained in the trough (*e*) against the cylinder, and complete the grading of them into a pulp. The tin-plate covering the cylinder is of course placed from the inside outwards, and the bur or rough edge, left round each hole, forms an excellent rasping surface.

\*2560. The chaff-cutter is used for cutting hay or straw into fragments not larger than chaff, to facilitate its consumption by cattle. There are numerous forms one of the best is that of Wear (*fig* 269), which is so formed, that in case of its being accidentally broken, it may be repaired by any common mechanic. The pressure of the straw is also capable of being regulated with great facility.

2561 The hay-binding machine is an invention by Beckway for weighing and binding straw or hay (*fig* 272.) It is a very ingenious apparatus, and may be useful to retail

269

270

is then set up in the sockets of the underside of the barrow. The frame (*c*) is then unfolded, and the axis of the steelyard or scale-beam (*d*), placed upon the standard as a fulcrum, supporting the frame (*c*) at the short end, and at the long end the counterpoising weight is suspended by a chain, and adjusted to the graduations upon the steelyard agreeably to the quantity of hay to be weighed. The bed of the frame (*c*) is then fastened down to the platform by means of the lever which held the wheel in the barrow. Two haybands are then placed between the hooks (*e e*), and extended along the bed of the frame (*c*). The truss of hay is then laid upon the bed of the frame (*c*) as shown by dotted lines, and the lever or latch underneath withdrawn, so as to allow the scale-beam to oscillate. The proper quantity or weight of hay being adjusted, the truss is bound round with the haybands, which were placed under it. This truss being removed, the same process is followed in weighing and binding every other truss, which is done without the smallest delay or inconvenience; when the whole quantity required is bound up, the apparatus is dismounted and packed together in five minutes, as *fig* 270. The respective implements, such as the knife, fork, pan, and every part of the machine, fitting together upon the barrow so as to secure the whole, are bound round by the chain and weight, and tightly packed for conveyance. (*Newton's Journal*, vol. i. p. 136.)

271

272

weight, and tightly packed for conveyance. (*Newton's Journal*, vol. i. p. 136.)

2562. The rope-twisting machine (fig 273), is a small wheel, the prolonged axle or spindle of which terminates in a hook, on which the rope is commenced. It is commonly fixed to a portable stand, but is sometimes attached to a threshing-machine. It is used for twisting ropes of straw, hay, or rushes, for tying on the thatch of ricks, and other similar purposes. It is also used to form very thick ropes for forming straw drains.

2563. The draught-machine, or dynamometer, is a contrivance invented for the purpose of ascertaining the force or power of draught, in drawing ploughs &c. Finlayson's (fig. 274.) is reckoned one of the best varieties for agricultural purposes.

2564. More's draught-machine is a spring coiled within a cylindrical case, having a dial-plate marked with numbers like that of a clock, and so contrived that a hand moves with the motion of the spring, and points to the numbers in proportion as the force is exerted. For instance, when the draught equals one cwt. over a pulley, the hand points to figure 1, when the draught is equal to two cwt. it points to figure 2, and so on. Till this very useful machine was invented, it was exceedingly difficult to compare the draught of different ploughs, as there was no rule to judge by but the exertions of the horses as apparent to the eye; a very undecisive mode of ascertaining their force.

2565. Braby's draught-machine (fig 275) consists of two strong steel plates, joined at the ends, and forming a spheroidal opening between them.

In using it, one end (a) is hooked on the muzzle of the plough or other implement, and to the other (b) the draught trees are attached. An indicator (c) points out the power applied, in cwts. It is evident that Braby's machine and Finlayson's act on the same principle, and that the latter, being more simple in the construction, must be a more accurate indicator, and less liable to go out of order.

2566. The weighing-cage (fig 276) is a contrivance made in the form of a sort of open box or cage, by which any small animal as a pig, sheep, calf &c. may be very easily and expeditiously weighed, and with sufficient accuracy for the farmer's purpose. It is constructed on the principle of the common steelyard, with a strong wooden frame and steel centres, in which the pivots of the lever are hung and upon the short side of the lever is suspended a coop, surrounded by strong network, in which the animal intended to be weighed is placed. The point of suspension is connected with the coop by means of two curved iron rods, which at the same time form the head of it a common scale being hung on the longer side of the lever.

2567. The cattle-weighing machine is a contrivance of the steelyard kind, for the purpose of weighing cattle and other animals alive. A machine of this sort is of importance in the grazing and fattening systems, where they are carried to any considerable extent, in ascertaining the progress made by the animals, and showing how they pay for the use of any particular kind of food, or what power it has in promoting the fattening process. Weir's variety (fig 277) is by far the simplest and most economical of these machines.

2568. The weighing-machine for sacks (fig 278.) is a convenient piece of barn-furniture on the steelyard principle, and so common as to require no description.

2569. *A potato-weighing machine* (fig. 279), of a very complete description, has been invented by Mr John Smith, of Edinburgh, and is figured in the *Edinburgh Penny's Transactions*, vol. vii. pl. III. It is on the principle of the steelyard, and chiefly intended for weighing grain, flour, potatoes, or any other commodity usually put into a bag for carriage or keep. The machine is portable, of easy use, and not liable to go out of order.

2570. *Rothson's former's steelyard* (fig. 280.) is well adapted for weighing and readily discharging bulky commodities. It consists of a longer and shorter beam, with a moveable weight, to be shifted along the former and a scale suspended to the latter. The longer arm, from its extremity being confined within a limited range, obviates the inconvenience of jerks and long vibrations, while an index upon it points out the required weight, by a counterpoise being slid backwards and forwards, till the point has been found when it acts as an equivalent. By turning a keeper fixed to the

scale, one end of it is opened, turning on a cylindrical hinge at the top, and the contents speedily discharged. These balances may be made of any size required, either to suit the purposes of the farm, or the household. Their simplicity secures them equally against expense of manufacture, and the risk of going wrong when in use. One weight only is required, the value of which, as a counterpoise, depends on its distance from the centre of motion, and it is so confined upon the long arm, that, though it has a perfectly free motion over all its length, it cannot escape at either extremity and consequently can never be lost, which is a great recommendation to the instrument. The simple manner in which one of the ends of the tin-plate scale opens up round a wire hinge is also very ingenious, and no less calculated to render the steelyard useful when weighing flour, grain, seeds, and such commodities. (*High. S. Trans.*)

2571. *The turnip-slicer* is of different forms the old machine works by hand, like a straw-cutter of the original construction but a better one consists of a hopper and knives, fixed upon a fly wheel. (fig. 281.) The turnips press against the knife by their own weight, and a man turning the wheel will cut a bushel in a minute. Gardener's turnip-slicer is a highly improved form of this machine.

2572. *The turnip-chopper* (fig. 282.) is perhaps a more useful implement than the turnip-slicer. It is first made like the common nine-inch garden hoe, forming an oblong square, with an eye to receive the handle, and from the centre of the first hoe, another hoe crosses it at right angles. On the reverse is a two-pronged fork, for the purpose of pulling up the turnips. The turnip being pulled out of the ground by the prongs, or the angles of the hoe, is immediately struck with it about the centre, which divides it into four; and if these four pieces are not small enough, the stroke is repeated upon each of the pieces until they are sufficiently reduced. The two stoutish prongs on the back or reverse part of the hoe, proceeding from the neck of the eye, besides their use in pulling up the turnips

with expedition, increase the weight of the hoe, which is in its favour, by lessening the force necessary to split the roots.

2573. *Of hand-drilling and sowing machines*, and especially of the former, there are a great many kinds, of various degrees of merit. The sort to be re-

recommended in any particular case will depend on the texture of the soil, one which would answer well in a soft soil or sand might not succeed in a stony or loamy soil. As the fashions of drills are continually changing, we advise intending purchasers to describe their soil and kind of culture, as whether raised or flat drilling, &c., to a respectable implement-maker, and try the kind he recommends. In the mean time we submit a few of the established forms.

2574. *The beam or potato dibbling machine* (fig. 283.) consists of a single wheel, set with dibber points, which may be placed wider or closer at pleasure. It is pushed along by one man, and succeeds on friable soils, but cannot be depended on when the surface is rough or tenacious. Potato sets to be planted after this machine should be cut with the improved scoop (2494.).

2575. *The common hand drill-barrow* (fig.

284) consists of a frame and wheel somewhat similar to that of a common barrow with a hopper attached to contain the seed. It is used for the purpose of sowing horse-beans, turnips, and similar seeds, upon small ridges. In using it, the labourer for the most part wheels it before him, the seed being afterwards covered by means of a slight harrow, or sometimes by a shallow furrow.

2576. *The broadcast hand-drill* (fig. 285) is chiefly used for sowing clover or other small seeds, with or without gram seeds. The operation, however, is much more fre-

quently performed by hand. Broadcast sowing by machinery drawn by horses or cattle, however, may be advantageously adopted on farms of the largest size, and where the soil is uniform in surface, in moisture, and in richness.

2577. *Coggins's dibbling-machine* (fig. 286) was invented in 1827, and appears very ingeniously contrived. The Mechanism is to be worked by the foot of the operator. The machine runs on wheels, and there are two conical dibbling irons, one larger than the other. These are ranged in a line with the delivering funnel of the drill, and at such distances apart as may be considered proper for discharging the seeds. A hopper (a) contains the seed, and such earthy materials as bone dust, or other manure in powder, as may be found necessary to deposit with the seed. There is a funnel (b) through which the seeds and manure are passed, and the conical dibbling iron (c) is worked by a handle (d). This dibbling iron and its handle are connected by two levers, of which the lower (e) hangs to the axle of the principal running wheel, and has at its front extremity a small cone (f), intended as a marker. There is an upper lever (g) which works the axle (h) of the cylinder, within

the hopper which delivers the seed. The foot of the operator is strapped to the lever, and by its pressure forces the dibbling iron into the ground. The inventor says that two machines may be used at the same time by the same man, one foot being strapped to each. (*Newton's Journal*, vol. ii. new series, p. 89.)

2578. The *turnip burrow-drill* sows a single row at a time but is of difficult management on the tops of ridges for this purpose, it is desirable to have two wheels, one to go on each side of the ridge. An improved variety of this machine (fig. 287) has a barrel of water (a) attached, which, by means of a tube, is dropped among the seed in the tract made by the coulter. This very useful appendage may be added to any drill-machine, whether worked by manual or animal labour.

2579. The *hand turnip-roller* (fig. 288) is used for rolling raised drills or ridges previously to and after sowing turnip-seed by a hand-drill. The use of such a roller leaves the ridges in a much better form for receiving the seed than a common cylindrical roller and after the seed is sown, when this roller is again used, the surface is left in the fittest state for retaining moisture, and for commencing the hoeing and thinning operations.

crums or pivots being in the standard (c c). These levers are connected together by a cord or chain (d d) passing over a pulley (e). To the lever (a) the cord (f) is attached which is also connected to the upper lever (g), this upper lever moving upon a fulcrum in the standard (c), works the pump rod (A). In order to put this apparatus in action, a man is to be seated on a transverse bar or rail (i), shown by dots near the end of the lever (a). The feet of this man are to rest upon the bottom lever (b) and by his alternately sitting upon the lever (a) and standing upon the lever (b) they are by the chain or cord (d) brought into the situation shown by the dotted lines and hence the lever (g) is raised and lowered for the purpose of working the pump. A weight is placed upon the lever (a) and made to slide, for the purpose of regulating the machinery and balancing the weight of the water or other matter raised. By these means it is evident, that a man can exert a greater power in proportion to the fatigue occasioned, than would be effected by the usual methods, such as turning a winch or moving a lever with the arms, &c. (*Newton's Journal*, vol. iii. p. 77.)

2580. *Dorn's machine for assisting human power* (fig. 389) consists in a certain arrangement of levers and pulleys, by means of which the weight as well as muscular strength of the labourer is intended to be brought into action, and hence to render his necessary exertions less laborious and fatiguing. Supposing the apparatus as applied to a pump then (a) and (b) will represent two levers, their ful-

crums or pivots being in the standard (c c). These levers are connected together by a cord or chain (d d) passing over a pulley (e). To the lever (a) the cord (f) is attached which is also connected to the upper lever (g), this upper lever moving upon a fulcrum in the standard (c), works the pump rod (A). In order to put this apparatus in action, a man is to be seated on a transverse bar or rail (i), shown by dots near the end of the lever (a). The feet of this man are to rest upon the bottom lever (b) and by his alternately sitting upon the lever (a) and standing upon the lever (b) they are by the chain or cord (d) brought into the situation shown by the dotted lines and hence the lever (g) is raised and lowered for the purpose of working the pump. A weight is placed upon the lever (a) and made to slide, for the purpose of regulating the machinery and balancing the weight of the water or other matter raised. By these means it is evident, that a man can exert a greater power in proportion to the fatigue occasioned, than would be effected by the usual methods, such as turning a winch or moving a lever with the arms, &c. (*Newton's Journal*, vol. iii. p. 77.)

2581. Other machines for particular departments, will be noticed in their proper places;

and some will be wanted which are not peculiar to agriculture, such as rat-traps (figs. 290 and 291), mouse and

mole-traps (fig. 292), a fowling piece for shooting birds, screws for deterring birds, and similar contrivances.

2582. The *grindstone* (fig. 293.) is a hand-machine that cannot be dispensed with in a farmery. The most improved sort has a cast-iron frame, which any person wishing to grind an instrument on may turn for himself, by operating with his foot

292

person wishing to grind an instrument on may turn for himself, by operating with his foot

on a treadle (a). This frame can be adjusted to a small or a large grindstone, or altered as the stone wears out, by the construction of the support for the gudgeon (b), a loose shield of sheet-iron (c) is used to protect the operator from the water thrown off by the wheel when in motion. (*Gard. Mag* vol. v)

2583. The essential hand-machines are the ladder, wheel and hand-barrows, winnowing machine, chaff-cutter, and turnip barrow-drill.

## CHAP II

### *Of Agricultural Implements and Machines drawn by Beasts of Labour.*

2584. The fundamental implements of agriculture are the plough, the harrow and the cart these are common to every country in the slightest degree civilised sufficiently rude in construction in most countries, and only very lately brought to a high degree of perfection in Britain. Dr Anderson (*Recreations in Agriculture &c.*), writing in 1802, observes, "that there are no sorts of implements that admit of greater improvement than those of husbandry on the principle of diminishing weight without in any degree abating their strength." Since that very recent period, great improvements have taken place in almost every agricultural implement, from the plough to the threshing-machine and though these have not yet found their way into general use, especially in England, they may be procured at the public manufactories of the capitals of the three kingdoms with no trouble. It is incredible what benefits would result to agriculture if proper ploughs and threshing-machines were generally adopted and if the scuffle or cultivator of which Wilkie's seems to be the most improved form, were applied in suitable soils, and under proper circumstances not to mention one and two horse carts, improved harrows, and the best winnowing machines. But the ignorance and antipathy to innovation of the majority of farmers in almost every country the backwardness of labourers to learn new practices, and the expense of the implements, are drawbacks which necessarily require time to overcome. It may also be observed, that, in the progress of improvement, many innovations which have been made have turned out of no account, or even worse than useless; and this being observed by the sagacious countryman confirms him in his rooted aversion from novelty and change. — In our selection, we shall pass over a great variety of forms, the knowledge of which we consider of no use, unless it were to guard against them, and shall chiefly confine ourselves to such as are in use at the present time by the best farmers of the best cultivated districts. These we shall arrange as tillage implements, sowing and planting implements, reaping machines, threshing machines, and machines of deportation.

#### SECT. I. Tillage Implements and Machines.

2585 The tillage implements of agriculture comprise ploughs with and without wheels, and pronged implements of various descriptions, as grubbers, cultivators, harrows, rollers, &c. We shall take them in the order of swing ploughs, wheel ploughs, pronged implements, harrows, rollers, &c.

##### SUBSECT. I. Swing Ploughs, or such as are constructed without Wheels.

2586. The plough, being the fundamental implement of agriculture, is common to all ages and countries, and its primitive form is almost every where the same. The furms used by the Greeks and Romans (see Part I Book I Chap 1 and 2.) seem to have spread over Europe, and undergone no change till probably about the 16th century, when they began to be improved by the Dutch and Flemish. In the 17th century the plough underwent further improvement in England and it was greatly improved in that following, in Scotland. There are now a great variety of excellent forms, the best of which for general purposes, is universally allowed to be what is called in England the Scotch plough, and in Scotland the improved Scotch plough. In speaking of the

implement we shall adopt the latter term, because the *unimproved Scotch plough* differs little from some old forms of the implement common to Europe from the time of the Romans. As the operation of ploughing, like many other operations in practical husbandry, must often vary in the manner of its being performed, it is evident that no one particular sort of plough can be superior to all others, in every season, and under every variety of soil or inclination of surface. The Scotch plough, however, and the variations of which it is susceptible, render it by far the most universal tillage implement hitherto invented or used.

2587. *Ploughs are of two kinds*: those fitted up with wheels, and called *wheel ploughs*; and those without wheels, called *swing ploughs*. The latter are the lightest of draught, but require an experienced and attentive ploughman to use them; the former work with greater steadiness, and require much less skill in the manager: some sorts, indeed, do not require holding at all, excepting at entering in, and turning on and off the work at the ends of the ridges. On the whole, taking ploughmen as they are, and ploughs as they are generally constructed, it will be found, that a district ploughed with wheel ploughs will show greater neatness of work than one ploughed with swing ploughs: but, on the other hand, taking a district where the improved form of swing ploughs is generally adopted, the ploughmen will be found superior workmen, and the work performed in a better manner, and with less expense of labour, than in the case of wheel ploughs. Northumberland in this respect may be compared with Warwickshire.

2588. In the construction of ploughs, whatever be the sort used, there are a few general principles that ought invariably to be attended to: such as the giving the throat and breast, or that part which enters, perforates, and breaks up the ground, that sort of long narrow beam, tapering, sharpened form that affords the least resistance in passing through the land; and to the mould-board, that kind of hollowed-out and twisted form, which not only tends to lessen friction, but also to contribute greatly to the perfect turning over of the furrow-slice. The beam and muzzles should likewise be so contrived, as that the moving power, or team, may be attached in the most advantageous line of draught. This is particularly necessary where a number of animals are employed together, in order that the draught of the whole may coincide.

2589. The construction of an improved Scotch swing plough is thus given mathematically by Bailey of Chillingham, in his *Essay on the Construction of the Plough on Mathematical Principles*, 1795. It had been previously aimed at by Small of Berwickshire, and subsequently by Vetch of Inchbonney, near Jedburgh, (*Highland Soc. Trans.* vol. iv. p. 243.), and more recently and completely in the *Quarterly Journal of Agriculture* for February 1829. Whoever wishes thoroughly to understand the construction of the plough, and the principles of its operation, are recommended to the last-mentioned very excellent paper which is too long to be given here, and which would lose half its value by being abridged.

2590. *Land, when properly ploughed*, Bailey observes, must be removed from a horizontal position, and twisted over to a certain angle, so that it may be left in that inclining state, one furrow leaning upon another, till the whole field be completely ploughed. The depth and width of the furrows which is most approved of by farmers, and commonly to be met with in the best-ploughed fields, are in the proportion of two to three; or, if the furrow be two deep, it must be three wide, and left at an angle of 45 to 46 degrees.

2591. Various forms have been given to the different parts of the plough, by ingenious persons, according to their different fancies, in order to diminish the weight of the draught, and to turn over the furrow, and leave it in its proper position, without tearing or breaking it.

2592. To have the line of draught at right angles to the horses' shoulders is of great importance in the formation of a plough: a circumstance of which the greatest part of the plough-makers are totally ignorant, although it is well known to every one that has the least knowledge of mechanics. If we take the angle that the horses' shoulders make with a perpendicular from the horizon, and continue another line at right angles to it, or parallel to the draught chain, the length of this line from the horse's shoulders to where it meets or crosses the coulters, at half the depth of the furrow, will be thirteen feet two inches for ordinary sized horses.

2593. *Length of beam*. If the plough be properly made, the line of draught should pass through the middle hole of the plough bridle at the point of the beam. This requires the beam to be seven feet long, to give it a proper height at the bridle.

2594. *Left side plane*. That part of the plough next the solid land should be made a perfect plane, and, run parallel to the line of draught; whereas some of the common ploughs are completely twisted in that part, and deviate more than two inches from the line of draught; this throws the plough to the left, and causes the hinder part of the mould-board to press hard against the furrow, and crush and break it, besides increasing the labour of the cattle.

2595. The position of the coulters must not deviate much from an angle of 45 degrees:

far, if we make it more oblique, it causes the plough to choke up with stubble and great roots, by throwing them up against the beam and, if less oblique, it is apt to drive the stones or other obstacles before it, and make it heavier to draw.

2596. The mould-board, for all free soils, and for working fallows, is generally most effective when it has a considerable concavity, but for breaking up clover leys, pasture, or any firm surface, and also for clayey soils, it is found to clean itself better and make easier work when it approaches nearer to a plane, and in very stiff clays, is formed with a concave surface. The lower edge of the mould-board, on the most improved forms, is in a separate piece, which, when it wears, can be taken off and renewed. The technical name of this slip of iron is the *swallow piece*.

2597. The materials with which ploughs are constructed is, generally, wood for the beam and handles, cast-iron for the head, side-plates, mould-board, and sole, and wrought iron for the share, coulter, and muzzles. But of late years, as consequence of the dearth of timber, and the cheapness of iron, they have been constructed wholly of the latter material, and with considerable advantage in point of strength and durability, and some also in point of convenience. Among the conveniences may be mentioned, the facility which they afford of bending the left handle to the right of the straight line (see fig. 2593. a), first introduced by Mr Wilkie of Uddington, (who, if not the inventor may certainly be considered the greatest improver of iron ploughs,) by which means the ploughman is permitted to walk with ease in the bottom of the furrow. The stilt or handles may also be joined to the body of the plough, in such a way as to admit of taking off and packing for a foreign country or raising or lowering the points of the handles according to the size of the ploughman, as in Weatherley's plough.

2598. Of *swag ploughs*, by far the best is the implement known in England as the *Scotch plough*. It is almost the only plough used in Scotland, and throughout a considerable part of England. It is drawn with less power than wheel ploughs, at least, those of the old construction, the friction not being so great and it probably admits of greater variations in regard to the breadth and depth of the furrow-slice. It is usually drawn by two horses abreast in common tillage; but for ploughing between the rows of the drill culture, a smaller one drawn by one horse is commonly employed. A plough of the swing kind, having a mould-board on each side, is also used both in forming narrow ridges for turnips and potatoes, and in laying up the earth to the roots of the plants, after the intervals have been cleaned and pulverised by the horse and hand-hoe. This plough is sometimes made in such a manner, that the mould-board may be shifted from one side to the other when working on hilly grounds by which means the furrows are all laid in the same direction. This will be found described as the *turn-wrest plough*.

2599. *Swing ploughs, similar to the Scotch plough*, have been long known in England. In Blythe's *Improver Improved* (edit. 1659), we have engravings of several ploughs and what he calls the "plain plough" does not seem to differ much in its principal parts from the one now in use. Amos, in an *Essay on Agricultural Machines*, says, that a person named Lummas (whom he is mistaken in calling a Scotchman, see Maxwell's *Practical Husbandman*, p. 191) 'first attempted its construction upon mathematical principles, which he learned in Holland but having obtained a patent for the making and vending of this plough, he withheld the knowledge of these principles from the public. However, one Pashley plough-wright to Sir Charles Turner of Kirkstatham, having a knowledge of those principles, constructed upon them a vast number of ploughs. Afterwards his son established a manufactory for the making of them at Rotherham. Hence they obtained the name of the Rotherham plough, but in Scotland they were called the Dutch or patent plough.' 'At length the Americans, having obtained a knowledge of those principles, either from Britain or Holland, claimed the priority of the invention, in consequence of which, President Jefferson, of the United States, presented the principles for the construction of a mould-board, first to the Institute of France, and next to the Board of Agriculture in England, as a wonderful discovery in mathematics.' (*Communications to the Board of Agriculture*, vol. vi. p. 437.) According to another writer the Rotherham plough was first constructed in Yorkshire, in 1790, about ten years before Lummas's improvements. (*Survey of the West Riding of Yorkshire. Sup. Encyc. Brit. art. Agr.*) We have seen it stated somewhere, that one of the first valuable alterations on the swing plough, of the variety formerly used in Scotland, was made by Lady Stewart of Goodtrees, near Edinburgh, grandmother to the Earl of Buchan. She invented what is called the *Rutherghlen plough*, at one time much used in the west of Scotland.

2600. The *Scotch plough* was little known in Scotland till about the year 1764, when Small's method of constructing it began to excite attention. (Small's *Treatise on Ploughs and Wheel Carriages*, 1784, and *Lord Kames's Gentleman Farmer*). This ingenious mechanic formed the mould-board upon distinct and intelligible principles, and afterwards made it of cast-iron. His appendage of a chain has been since laid aside. It has been disputed, whether he took the Rotherham, or the old Scotch plough, for the

bank of his improvements. The swing plough has been since varied a little, in some parts of Scotland, from Small's form, for the purpose of adapting it more completely to particular situations and circumstances. Since 1810, this plough has been very generally made entirely of iron. In Northumberland the mould-board is made less concave than in Berwickshire, and in Berwickshire it is even less concave than in Small's plough. Different degrees of concavity in the mould-board suit different soils—soft and sandy soil requires most, and a loamy or clayey soil least, concavity. The following are the principal varieties of the improved Scotch plough at present in use in the most improved districts of the north, and among scientific farmers in all countries.

2801. *Small's plough.* The mould-board is more concave than in most other varieties, and this may be considered its characteristic as compared with these varieties. It is sometimes drawn by a chain proceeding from the muzzle to the head, in order to lessen the strain on the draught-beam, and in that case it is called Small's chain plough. It is commonly made of wood and iron (fig. 294. a, as seen from the right side, b from above), but also entirely of iron.

2802. *The Northumberland plough, and the Berwickshire plough,* are very nearly the same implement differing from Small's plough in having the mould-board less concave.

2803. *Wilkie's swing plough,* the best iron swing plough in Scotland, (fig. 295. a, as seen from above, b the left side) is formed entirely of iron except the points of the handles. Its characteristic, in point of form, is a longer mould-board with a greater twist in it, the object of which is, to reverse the furrow more completely in light or highly pulverized soils.

2804. *Finslayson's iron ploughs* (figs. 296 to 299.) are, as he informs us (*British Farmer*, p. 9), constructed in imitation of those of Wilkie, but with improvements and modifications adapted for particular circumstances.

2805. *The heath or self-cleaning plough, or red plough,* (figs. 296, 297), is formed with the beam so curved vertically (fig. 296.), or divided and curved horizontally (fig. 297),

as to leave no resting place for stubble, heath, or other vegetable matter, at the top of the scutler, where in rough grounds, with ploughs of the ordinary construction, it gets entangled and stops the work.

2806. *Finslayson's Kentish skeleton self-cleaning plough* (fig. 298.) is intended as a substitute for the common Kentish turn-wrest plough. "The soil, in great part of Kent, is of a peculiarly adhesive clay. When this soil is between the wet and dry, it adheres

as the body of the plough like glass, by which the draught is increased probably double or treble." By substituting three or four iron rods for the mould-board, the soil is pre-

297

vented from adhering, while the operation of ploughing is at the same time performed in an equally perfect manner with two horses as with four. This is accounted for 'by the whole surface of this plough not being more than one third or one fourth the surface of other ploughs.' In like manner, when it is necessary to dig or trench very strong clayey soil between the wet and the dry, the operation is performed with much greater

298

ease by a two-pronged fork. It is important to agriculturists to know the opinion and experience of a man of so much science and extensive practice as the late Mr. Finlayson, who says, "from my own experience I have no hesitation in saying that the most adhesive land may with ease, be ploughed by the skeleton plough, and one pair of good horses." (*British Farmer*, p. 185.)

2907 *Finlayson's line plough* (fig. 299.) is characterised by a rod (a), which proceeds

299

from the sheath of the plough to the maul, which is put on when the plough is drawn by horses in a line—a very disadvantageous manner, but yet common in many parts of England.

2599. The *Somerville swing plough* is known by its mould-board, a part of which is rendered moveable by hinges; the advantage of this is, that the furrow can be laid more or less flat at pleasure. "Mould-boards," Lord Somerville observes, "formed to lay furrows in lay, so as to give the most soil to barrows, cannot be of that form best calculated to make good work in stirring earth; more especially the last, which ought to be thrown up in small seams, as it were, that the seed may be duly buried. It has hitherto held necessary to rip off the plate for this purpose, and drive in wedges, by which the mould-plate must be injured. From the trouble attending this operation, it has generally been omitted, and the land, of course, imperfectly worked. But this inconvenience may be remedied, and the mould-board be adjusted with great facility and expedition, by the following means — When the mould-board is formed, and its plate fixed as usual, let the hind part be cut off, and again connected with the fixed part of mould-board by means of *flat hinges, or of thin flexible plates of tempered steel, or of hard hammered iron*, so as to admit of that part being set to have different inclinations with the fixed part of the mould-board — by means of a screw passing from the inside through the lower part of the handle of the plough, opposite the back of this moveable piece, the screw may be made to keep it at any desired degree of inclination, according to the nature of the work to be performed." — This plough, however, has been but little used, and does not seem to meet the approbation of the best cultivators.

\*2600. *Turn-wrest swing ploughs* are such as admit of removing the mould-board from one side to another at the end of each furrow, for the purpose of throwing the earth removed always to one side. Their principal use is in ploughing across steep declivities, in order that the furrow-slice may always be thrown down. Wherever it is practicable, however, it is best to plough obliquely up and down such declivities, because the other practice soon renders the soil too rich and deep at bottom, and too thin and poor at top.

2610. *Gray's turn-wrest swing plough* (fig. 300.) is one of the most scientific implements of the kind. The beam, head, and sheath, must always be placed in the direction of a line passing along their middle, and the two handles must be placed equidistant on each side of that line. There are two mould-boards and two coulters, and a mould-board is produced on either side, at pleasure, by moving the lever (a) between the plough handles from the one side to the other. The line of draught can be shifted with equal ease and expedition, and at the same time one of the coulters raised up clear of the land, and placed along the side of the beam, whilst the other is put down, and placed in a proper position for cutting off the furrow-slice from the furrow ground. All this is performed at once, without the ploughman's changing his position, by means of two levers (b, c, and d, a). We have already noticed (2597) the mode in which the double-moulding or earthing-up swing plough may be rendered a turn-wrest plough, of a less perfect kind.

2611. *Weatherley's moveable stilt plough* (fig. 301) is characterised by certain joints in the stilts (a c), which admit of raising or lowering the handles at pleasure, so as to suit the height of the ploughmen. They also admit of taking off the stilts for the convenience of packing.

These joints are the invention of Weatherley, a Northumbrian agriculturist in the service of Prince Esterházy. The plough is manufactured by Weir of London, who commonly adds to it the improved draught tackle (b).

2612. *The riding plough* is any of the above implements on a smaller scale, to be used for the operation of ribbing, or laying leys or stubbles in small ridges.

2613. *Duck's stem-coulter plough* (fig. 302.) is said to be a valuable implement, though not much in use. By it the ground may be opened to any depth in separate horizontal portions of earth, and, as the weeds or grassy surface are turned down in the first operation, and covered by fresh earth or mould from beneath, a larger proportion of nourishment is supposed to be provided for the crop, while at the same

time it is rendered more clean, and the inconvenience of the roots of the grasses or other plants wholly got rid of. It requires a strong team in the heavier sorts of soils, but this is in some degree counterbalanced by the circumstance of one such ploughing being mostly sufficient for the crop. It is, says a late theorist, consequently evident that, considering the number of ploughings generally given in the ordinary way of preparing lands for a crop of barley or turnips, and under the following system for wheat, and the labour and expense in the latter case, in raking, picking, and burning weeds, the advantages of this plough are probably greater than is generally supposed. It has also advantages in another point of view, which is, that the soil is increased in depth, and the parts of it so loosened and broken down that the fibrous roots of the crops strike and extend themselves more readily in it, and of course are better fed and supported. In thin and sandy soils it is more particularly useful, because it cuts off all which is on the surface, at the depth of an inch or an inch and a half, in order to its being laid in a state of decay, for a future crop; by which an increased depth of soil is given to every subsequent course of crops, which often acts as a support, to keep up manures near the surface, as their running through such soils too quickly is a disadvantage. It is also capable of being made use of without a skm coulter as a common plough.

2614. A skm-coulter may be added to any other plough, and may be useful in turning down green crops and long dung, as well as in trench ploughing. But in most instances it is thought a preferable plan, where the soil is to be stirred to an unusual depth, to make two common swing-ploughs follow each other in the same track; the one before taking a shallow furrow and the other going deeper, and throwing up a new furrow upon the former.

2615. The *double share plough* is distinguished by having one share fixed directly over the other. It is made use of in some of the southern districts, with advantage, in putting in one crop immediately after ploughing down another, as by it a narrow shallow furrow is removed from the surface, and another from below placed upon it, to such depth as may be thought most proper, — it being capable of acting to ten inches or more. In this manner many sorts of crops, such as rye and other green crops that have much height of stem, may be turned down without the inconvenience of any of the parts sticking out through the seams of the furrow slices, by which the farmer has a clean surface of mould for the reception of the grain.

2616. The *saving plough*, or *trenching plough*, is sometimes employed for the purpose of loosening the soil to a great depth, without bringing it up to the surface; a mode of operation which is particularly useful for various sorts of tap-rooted plants, as well as for extirpating the roots of such weeds as strike deep into the ground. For these purposes it may be employed in the bottom of the furrow after the common plough. It is constructed in a very strong manner having a share but no mould-board. The share raises the earth in the bottom of the furrow, and passing on under what it has raised, leaves the soil where it was found, but in a loosened state.

2617. *Somerville's double-furrow plough* (fig 303.) is obviously advantageous in per-

303

forming more labour in a given time, with a certain strength of team, than other sorts of ploughs, as producing two furrows at a time. It has been found useful on the lighter sorts of land where the ridges are straight and wide, though some think it more confined in its work than those of the single kind. The saving of the labour of one person, and doing nearly double the work with but little more strength in the team, in the same time, recommend it for those districts where four-horse teams are in use. This plough has been brought to its present degree of perfection by Lord Somerville, especially by the introduction of the moveable plates already mentioned (2607), at the extremities of the mould-board, as in His Lordship's single plough. But, as observed by an excellent authority, "with all the improvements made by Lord Somerville, it can never come into competition, for general purposes, with the present single-furrow ploughs. Lord B. admits, that it would be no object to invade the system already established in well cultivated counties though, where large teams are employed, with a driver besides the ploughman, it would certainly be a matter of importance to use this plough, at least, on light friable soils. " Their horses, he says, " will not feel the difference between their

own single furrow, working one acre, and the well constructed two-furrow plough, with two acres per day; here is no system deranged, and double work done." (*Comm. B. A.* vol. II.) This plough is also of particular value for ploughing up and down steep. (See 2627.)

2618. The *Argentine plough* differs from Small's, or any single swing plough, in having no coulters fixed in the beam, but, in lieu of this, a fin or knife rising from the left side of the share, which serves the purpose of slicing off the furrow as well as the coulters. This fin or feather must be placed at the same angle as the coulters and should terminate in a lance-like shape, in order to furnish the least obstruction to stubble, weeds, or stones. This plough is not liable to be choked by stubble, or thrown out by catching small stones between the points of the coulters and sock. It is found particularly useful in taking the earth away from the sides of a drill crop as its broad upright feather, which operates as a coulters, completely shields the plants from all risk of earth falling on them from the left side of the plough, while, at the same time, the ploughman ascertains to a certainty, that the part of the plough below ground approaches no nearer to the roots of the plants than the upper part does to their leaves; so that he can bring the plough to slice off the earth close in upon their sides, if necessary. In point of draught it is precisely the same as the common plough.

2619. The *double mould-boarded plough* is a kind of plough often used with advantage in clearing out furrows, in setting potatoes, cabbages, and other similar crops, and in earthing up such as are planted in wide rows. Those whose mould-boards move on hinges, and may be set wide or narrow at pleasure, are the most convenient. A variety of this plough, made by Werr of London, admits of removing the mould-boards, and fixing in curved coulters and hoes, for cleaning between drilled turneps and similar crops.

2620. The *blast* is almost the same thing as the double mould-boarded plough, and the one is commonly sold for the other, with no loss to the purchaser. It has two mould-boards, one on each side of the beam. It is used in some soils in forming a ribbed or ridged bed for wheat or other grains, by which means, when the grain is sown over the ribs or ridgelets in the broadcast manner, as it falls for the most part into the furrows, or is harrowed into them, it comes up in rows. It is also used in earthing up crops and sometimes, in Flanders, but never by the best cultivators in England, in giving the first furrow to stubbles.

2621. The *marking plough* is used in straightening and regulating the distance of ridges where the drill system is practised. Any plough with a rod fixed at right angles to the beam, and a short piece depending from this rod, will trace a line parallel to the furrow drawn by the plough, which line will serve for a guide as to the width of ridges, &c.

2622. *Clymer's plough* (fig. 304) is a recent modification of the implement, formed entirely of iron, and chiefly remarkable for the absence of the coulters or rather its attachment to the breast, and for the share, mould board, and other parts which move under ground, being composed of distinct pieces of cast-iron. This is considered as cheaper to commence with and easier to repair, because any one part may be renewed of the same material without deranging the rest whereas renewing or repairing wrought-iron shares, mould-boards, or coulters, is found in many districts both difficult and expensive. It has never come into use.

2623. *Stothard's plough* is characterised by a perforated mould-board. The holes may be in any form or dimensions and their object is to allow the air to pass through, and thereby prevent the adhesion of wet earth, which it is contended adheres in ordinary ploughs with such a degree of tenacity as greatly to increase the friction, and diminish the speed of the horses. (*Newton's Journal*, vol. II. p. 335.)

2624. *Morton's trenching plough* (fig. 305.) has two bodies (a b), the one working four

304

305

or six inches deeper than the other. The first (a) cuts or pares off the surface to the required depth, say five inches, and turns it over into the furrow, ten or twelve inches deep, made by the main body. The second body generally works from ten to twelve inches deep, but might be made to work to the depth of thirteen or fifteen inches upon its mould-board is formed an inclined plane, extending from the back part of the feather of the sock or share (c) to the back part of the mould-board (d) where it terminates about six inches above the level of the sole (e). This inclined plane raises the soil from the bottom of the furrow, and turns it over on the top of that which has been laid in the bottom of the previous furrow by the body (a) going before.

2635 *Gladstone's water-furrowing plough* (figs. 306. and 307) is used for cleaning out the furrows of a new-sown field, when the nature of the soil, or the inclination of the surface, requires extraordinary attention to leading off the rain water. The beam (a), handles (b), and sole (c), of this plough are formed in the usual manner

of double mould-board ploughs. The sole is five inches square, for the purpose of forming a square bottom to the furrow. The two mould-boards (d) are loose, so as to rise and fall with the depth or shallowness of the furrow, being fastened only by the centre pin (e) to the upright (f). The mould-boards, or wings, as they are called, are kept extended by a piece of iron (g) and this piece of iron has a number of holes in it, so that, by means of a pin (h) it may be raised or lowered at pleasure, according to the depth of the water furrow. The mould-boards are made of wood. Any old plough may be converted into one of this description for a few shillings.

2626 *Drawing ploughs* are of various kinds, but none of them are of much use the work can always be done better, and generally cheaper by manual labour. As most of these ploughs have wheels, we have included the whole of them in next subsection.

## SUBSECTION 2. *Wheel Ploughs.*

2627 *Wheel ploughs* are of two kinds those and which are by far the most common, where the wheel or wheels are introduced for the purpose of regulating the depth of the furrow, and rendering the implement more steady to hold and those where the wheel is introduced for the purpose of lessening the friction of the sole or share. This last description of wheel plough is scarcely known, but it promises great advantages. The former is of unknown antiquity, having been used by the Romans.

2628. *Ploughs with wheels for regulation and steadiness* vary considerably in their construction in different places, according to the nature of soils and other circumstances but in every form, and in all situations, they probably require less skill in the plough man. Wheels seem, indeed, to have formed an addition to ploughs, in consequence of the want of experience in ploughmen and in all sorts of soil, but more particularly in those which are of a stony and stubborn quality, they afford great assistance to such ploughmen, enabling them to perform their work with greater regularity in respect to depth and with much more neatness in regard to equality of surface. From the friction caused by the wheels, they are generally considered as giving much greater resistance, and consequently demand more strength in the team that is employed and, besides, are more expensive in their construction, and more liable to be put out of order as well as more apt to be disturbed in their progress by clods, stones, and other inequalities that may be on the surface of the ground, than those of the swing kind. It is also observed, "that with wheel ploughs workmen are apt to set the points of their shares too low, so as by their inclined direction to occasion a heavy pressure on the wheel, which must proceed horizontally the effect of this struggle is an increased weight of draught, infinitely beyond what could be supposed for which reason, the wheel is to be considered as of no importance in setting a plough for work but passing lightly over the surface, it will be of material aid in breaking up old leys, or ground where flints, rocks, or roots of trees occur, and in correcting the depression of the share from any sudden obstruction, as well as in bringing it quickly into work again, when thrown out towards the surface. (*Communications to the Board of Agriculture*, vol ii p 419.)

2628. The improved Scotch plough, with one or sometimes two wheels (fig. 308.), fixed near to the end of the beam, without any carriage, goes very light, and is very useful, with alterations as are necessary requiring very little time or trouble. Where two wheels

are employed, the plough does very well without a holder on a good tilth or light sward, where there are few stones, except at the setting in and turning out. Wheel ploughs should, however, probably be seldom had recourse to by the experienced ploughmen, though they may be more convenient and more manageable for those who are not perfectly informed in that important and useful art.

2630. The Devonian plough (fig. 309.) was once considered a good wheel plough. It has its principle of draught given it in a very effective manner by an ingenious contrivance of iron work, in which, according to Lord Somerville, "the point of draught is perpendicularly above the point of traction, or the throat or breast where the share sits on."

2631. The Kentish and Herefordshire wheel ploughs are extraordinary clumsy implements of very heavy draught, and making, especially the former, very indifferent work. They were figured by Blythe in the beginning of the seventeenth century and seem to have received no improvement since. The Kentish plough is generally made with a turn-wrest, in order always to turn land downwards in ploughing a hill, but thus, as Lord Somerville remarks, soon renders the summit of the hill or the upper side of the field, where such a practice is persisted in, destitute of soil. A much better mode is to plough up and down the steep, or diagonally across it. In either case the double mould-board plough, invented by His Lordship, is of singular use, as one furrow only need be taken in going up and two in coming down.

2632. The Norfolk wheel plough (fig. 310.) has a clumsy appearance, from the great bulk of its wheels and their carriage; but in light friable soils it does its work with neatness, and requires only a small power of draught.

2633. Ploughs with wheels for diminishing friction are of comparatively recent date. Morton, of Leith walk, in 1813, conceived the idea of

introducing into the body of the plough a wheel about 15 inches in diameter, to act as the sole, and made several exhibitions of a plough so constructed before the Dalketh Farming Society. (*Gard. Mag.* vol. v.) Wilkie, of Uddington, brought forward a similar plough in 1814, and Plenty, of London, in 1815. Liston, of Edinburgh, a few years afterwards, brought forward a plough on the same principle but it never came into use. Plenty's friction wheel plough has been occasionally used in England. It has two wheels under the beam, and one behind the sole; and, while the same plough with two wheels requires a power of 4 cwt., those with a third or friction wheel, as Mr. Plenty informs us, require only a draught of  $2\frac{1}{2}$  cwt.

2634. Wilkie's single horse wheel plough (fig. 311.) was invented by the late Mr. Wilkie, and described by him in the *Farmer's Magazine* for November, 1814. It has the

wheel (d) placed behind the sole, which, besides considerably reducing the weight of draught, is found to give a degree of steadiness seldom exceeded in the use of the common plough, except when quite new, or recently repaired with a new sock and sole-shoe. At that period, when the back end of the sole is quite full and square, the common plough (when well constructed) goes as well as can be wished for but, by the great friction of the sole, the back end of it soon becomes convex, and, consequently the plough loses the steady support of the extremity of the heel or in other words, in proportion as the sole becomes more convex, the fulcrum of the lever is extended considerably forward, so as to be too near the centre of gravity. When that is the case, the least obstruction at the point of the share throws the plough out of the ground. In order to remedy or counteract that tendency, the ploughman is obliged to raise the point of draught at the end of the beam but this expedient, although it gives the plough more hold by the point of the share, is attended with another inconvenience fully as bad as the former for when the point of the share meets with an obstruction as before noticed, the heel of the plough is raised, on account of the point of draught being fixed above the direct line of traction. Thus, the common plough, when the sole becomes convex, is made to go very unsteadily and often requires the utmost attention and exertions of the ploughman to direct it. What is stated above, however can only apply to the common plough when out of order by the sole becoming convex.

311

2635. *Placing the wheel.* In order to understand in what manner the wheel ought to be placed so as to reduce the friction, it may be necessary to remark that one of the first properties of a plough is to be constructed in such a manner as to swim fair on the sole. This depends principally on the form of the sole, and position or inclination of the point of the sock together with the point of draught at the end of the beam (a). If these are properly adjusted, the pressure or friction of the sole will be uniform from the point of the share (b) to the back end of the heel (d) or in other words, the friction will be balanced between these two points by means of the beam (a) acting as a lever the heel (d) being the fulcrum, and a point over the share (c) the centre of gravity.

2636. *The centre of gravity* or of resistance will be extended nearer to the point of the share (b), in proportion as the soil has acquired a greater degree of cohesion as in old pasture ground or strong clays. But, wherever the point of resistance meets, it is evident that the point of draught at the end of the beam must be placed so as to balance the friction of the sole between its extreme points (b and d). Viewing the machine, therefore (with regard to the friction of the sole) merely as a sledge carrying a considerable weight, by which it is pressed equally to the bottom of the furrow at the extreme points (b and d) it is clear that, by substituting a wheel at the one point (d) the one half of the friction of the sole will be thrown on the wheel. The draught is reduced by the wheel from forty to sixty six pounds, or from one seventh to one fifth (two hundred and eighty pounds being the power of one horse.)

\*2637 *Wilkie's improved friction-wheel plough for two horses* (fig. 312.) was invented by the late Mr Wilkie in 1825, and is manufactured by his son at Uddington, near Glasgow. We consider this as by far the most perfect implement of the plough kind that has hitherto been produced. The wheel (e) is placed so as to incline from the

312

perpendicular at an angle of about 80 degrees; and, following in the angle of the furrow cut by the coulter and share, it ensures a greater degree of steadiness in the motion of the plough than when rolling only on the bottom of the furrow.

The sock or share is of cast-iron, which is a great saving both in first cost and repairs; costing only one shilling and ploughing at an average upwards of ten acres. Only the coulter requires to be taken to the smithy, the share being renewed by the ploughman at pleasure. The wheel, which is of cast-iron, will last many years. The draught of this plough has been proved at a public ploughing match in 1828, to be fully 50 per cent less than that of the common scoring plough of the most improved form. The price is also lower than that of any iron plough now in use. Mr W has lately made some of these ploughs with a piece of mechanism attached to the wheel, by the revolution of which, the quantity of ground passed over by the plough may be indicated. (*Gard. Mag.* vol. v.)

2638. *The paring wheel plough* is of various forms, though it is an implement seldom required. It is used for paring the surface of old grass lands, or leys on clay soil, where the turf is to be burned. A variety in use in the fen districts (fig. 313.).

has a wheel (a) which cuts the turf, instead of a coulter, a broad flat share which slices it, with a sharp fin or turned-up part at the extremity (c), which cuts the turf on that side, thus turning it over in slices about a foot broad and two inches deep. There is a foot (b) from the forepart of the beam, which serves to prevent the share from going too deep.

2639 Clark's draining plough (fig. 314.) was found to answer well in meadow ground near Belford in Northumberland, but could not be drawn in stiff clay

314

with the force of eight horses.

2640 Gray's draining plough (fig. 315.) seems one of the best. The beam is strongly fortified with iron, and is always kept at a proper distance from the surface of the ground, and also the

315

depth of the drain regulated by two wheels (a c) which turn on an iron axle, and roll upon the surface on each side of the drain. The middle coulter is made to cut perpendicularly consequently, the side coulters will cut the two sides of the drain at an equal slope. When this machine is at work, the earth of the drain is cut in the middle by the foremost coulter, and on each side by the other two coulters. Then the sharp point of the share will cut up that earth from its bed, and, as the machine advances, it must second on the surface of the inclined plane at the same time, the fore-ends of the mould-boards, following in the track of the middle coulter, will divide the slices of earth, as it rises, into two equal parts, turning these parts gradually to each side, and, as the back-ends of the mould-boards extend further than the breadth of the drain above, the portion of earth so raised will be placed upon the firm ground, leaving the drain quite open. The frame into which the axle is fixed may easily be either raised up or depressed, as the drain is to be cut deep or shallow and the two outside coulters can easily be placed more or less oblique, so as to cut the sides of the drain at a greater or less slope, as may be found necessary. (Gray's Implements, &c. 4to.)

315

a

2641 Marton's draining plough (fig. 316.) has three coulters (a b c), two mould-boards (d e), and one share (f). The mould-boards have an inclined plane, formed upon

316

such (f c), which rises from the share backwards to such a height above the level of the sole as the drain is required to be made deep. The middle coulter separates the soil to be lifted into two parts, and each part is raised to the surface by the inclined planes on the mould-boards. The usual dimensions of the drain so formed are 10 or 12 inches deep, 8 or 9 inches wide at bottom, and 14 or 15 inches wide at top but the construction may be adapted to a smaller or a larger drain, or for cleansing out drains already made.

2642. The gutter plough (*fig. 317*) is made use of for forming gutter drains in grass lands, where the soil is of a retentive nature. The power of six horses is required in drawing it for the first time; but four horses are found sufficient for opening the old gutters.

2643. The mole plough (*fig. 318*) was invented by Adam Scott, and improved by Lambert of Gloucester shire. It is said to be an implement which, in ductile soils and situations, as in pleasure-

317

318

grounds, and where much regard is had to the surface-appearance of the land, may be of considerable benefit in forming temporary drains. It makes a drain without opening the surface any more than merely for the passage of a thin coulter, the mark of which soon disappears: it is chiefly

employed in such grass-lands as have a declination of surface, and where there are not many obstructions to contend with: but some think it may be used in other kinds of land, as on turnip-grounds that are too wet for the sheep to feed them off, or where, on account of the wetness, the seed cannot be put into the earth. With this plough the drains should be made at the distance of ten or fifteen feet in straight lines, and also contrived so as to discharge themselves into one large open furrow or grip, at the bottom of the field. As it requires great strength to draw this implement, it can only be used where a good team is kept.

2644. Lambert not only brought this plough to its present shape: but, finding the surface greatly injured by the feet of so many horses as were found necessary to draw it, he invented a piece of machinery (*fig. 319*), consisting of a windless, frame, and anchor,

319

by which it is worked by the labour of four men. Young and other members of the Board of Agriculture, expressed themselves greatly enamoured of this plan: but it is obviously too complicated and expensive for general use.

2645. A subsequent improvement, by Lambert, consisted in the addition of a gin-wheel and lever, by which the machine was worked by one horse walking round it, as in a common horse-mill, and this last form has again been improved by the late mechanist, Wear, of Oxford-street, London by the addition of a vertical cylinder, which winds up the chain without any attention from the driver. Wear has also simplified and strengthened this machine in other respects, so that his modification of it (*fig. 320*.) is,

320

as present, by far the best. Still we think it an implement that very seldom can be profitably used: that this may be the case, the surface of the field

must have a natural drainage, by lying in one even slope or slopes; it must be in pasture, and the soil must be of uniform consistency, and free from stones. But even where these favourable circumstances combine, we think two swing ploughs, with fluted shares, following in the same track, would effect the same object sufficiently well for all agricultural purposes; and for drains in ornamental grounds, no machine will ever equal manual labour.

3646. *The Duke of Bridgewater's draining plough* (fig. 331) is used for making open drains of a small size (e), regular shape, and from five to six inches deep. The

331

share (a) has a coulter (b) fixed to it, projecting upwards, to cut one side of the drain, and another coulter (d) fixed to the beam and also to the share at its lowest end. The turf which is thus cut out passes between the coulter (d) and the mould-board (c), and is thus lifted clearly out of the trench. The depth of the drain is regulated by the wheels at the fore end of the beam (f). This plough is drawn by four or six horses.

3647. *Various draining ploughs* have been invented and tried by Arbuthnot, Makie, M Douglas, Green, Pearson, and others. Pearson's will be afterwards figured and described.

3648. *The pressing plough* is properly a roller, and will be found noticed among machines of that class.

3649. *The only essential plough* to be selected from these three sections is the improved Scotch swing plough, with or without one or two wheels, according to circumstances and with the mould-board, share, and coulter set to suit different soils, as flinty, chalky, &c. or soils in different states of culture, as old turf, heath, steep banks, ley, &c.

### SECTION 3. Tillage Implements, known as Scarifiers, Scarifiers, Cultivators, and Grubbers.

3650. The use of pronged implements, as substitutes for the plough, is of comparatively recent date. They differ from the plough in stirring the soil without reversing its surface or altering its form, unless, indeed, they in some cases tend to even or level inequalities: they act both as the plough and harrow at the same time, and on suitable soils, and at proper seasons, much more labour is effected with less expense of men and cattle. Wherever therefore, lands require to be stirred for any purpose except that of reversing the surface, or laying them into beds or ridges, recourse may be had to pronged tillage implements, such as we are about to describe.

3651. *In estimating the value of pronged tillage implements*, General Boscawen (*New System of Cultivation*, 223) applies the principle of leastening power and expending time. He says, if we apply the principle of petty operations to any stiff land, by taking that depth of furrow which can easily be ploughed with two horses, and repeat the operation (or plough the land a second time) we shall arrive at the end proposed, that is, the same depth of ploughing, with absolutely less exertion of animal strength than if we were to plough the same depth with four horses at one operation.

3652. This may be illustrated by supposing the resistance to the plough to be in proportion to the square of the depth of the land. If so, and we are to plough at once with four horses, six inches deep, the resistance at that depth would be  $6 \times 6 = 36$  but if with the same four horses, using two at a time, we plough the same depth of six inches at two operations, taking only three inches at each then the square of the first depth is 9, and the square of the second, 9; making 18 for the total resistance, or the power expended by the two horses, in ploughing six inches deep, at two operations.

3653. *A further illustration* may be made by supposing the same four horses, which had ploughed at once six inches deep, had overcome the resistance of  $6 \times 6 = 36$ , applied, separately, to four light ploughs, or other implements, and to plough only 1½ inch deep at a time, and to go over the same land four times. In this case the sum of all the resistances to be overcome, or the animal force expended, in these repeated ploughings, would be no more than 9 instead of 36, because the square of 1½ = 2¼, which multiplied by the four ploughings, gives 9, or only one fourth of the power expended in ploughing at once six inches deep. Hence it appears, that in ploughing six inches deep, with four horses, each horse exerts a force = 9 whereas in taking only 1½ inch deep, the force he exerts is not more than 2¼.

3654. *Further* supposing that a horse exerts, in drawing a plough, a force of 160 pounds, it is evident, if four horses are ploughing six inches deep, the total force exerted will be 640 pounds, or 160 pounds by each; but if they be required to plough one inch and a half deep at a time, then the total force expended by the four horses will be only 160 pounds, or 40 pounds by each horse.

3655. *Definition.* This leads General B. to the principle on which his small scarifiers are constructed. "They have," he says, "four handles in the hind bar, and I will suppose that there are four harrows (instead of three) in the front bar, so that each scarifier may be considered as four small ploughs, with four shares and four coulters. If we suppose one horse attached to this implement, and that the force he exerts is 160 pounds, it is obvious that in emptying to the depth of one inch and a half, he will thrust them 160 pounds upon the four points of them, or a force of 40 pounds upon each pair. But, in fact, the force required to draw the scarifier will be considerably less than to draw any form of plough, because the line, or sharpness, being much thinner and sharper than a ploughshare and mould-board, will of course meet with much less resistance in stirring the soil." General B. goes on to relate some experiments by which he concludes his line "is clearly proved that the least expensive method of preparing the land for wheat, after tares, horse, peas, or clover, is simply by using the scarifier." This we conceive is emptying

the use of the monitor much too far. We think it is a sufficient illustration of its value that it may be used in plowing lands on which potatoes or turneps have grown, or that have been ploughed in autumn or during winter, so that a crop may be sown in spring without further use of the plough. In working fallow, and preparing for turnips and potatoes, it may serve two or three furrows. (*Supp. Eng. Br. art. Agr. and Farm. Mag.*)

3256 *Willis's parallel adjusting brake, or cultivator* (*fig 322.*), appears to us decidedly

the most perfect implement of this description. The prongs of such implements, mechanically considered, are bent levers (*fig 323.*), of which the fulcrum is at *a*, the power at *b*, and the weight or resistance at *c*. The improvement of Mr. Wilkes consists in adopting a curve (*d b*), for the resisting part

of the lever, and thus bringing into action the principle of tension, instead of mere resistance to fracture in the resisting part of the lever (*Gard. Mag.* vol. v p 655) The parallel movement has the advantage of instantaneously adjusting the implement to any depth that may be required. Besides the ordinary purposes of a cultivator, this brake or harrow may serve the other tillage purposes following. — 1 By attaching tines with triangular feet, it makes a scarifier; or, in place of tines, one large triangular blade suspended from each of its extremities or angles. 2 By substituting cutting wheels in place of tines, it is converted into a sward cutter. 3 From its extreme accuracy of adjustment it will make an excellent drill, or ribbing machine, and may be made to sow at the same time. And 4. and finally if steam is destined ever to supersede the labour of horses in drawing the plough, this machine, from its peculiar formation and mode of management, will afford the greatest facility for trying the experiment, as it may be made to take a number of furrows at once

3257 *Fulleyson's self-cleaning cultivator, or harrow* (*fig 324*) is formed of iron, and,

according to the inventor, has the following advantages. — 1 From the position in which the tines are fixed, their points (*a a a a*) hanging nearly on a parallel to the surface of the land, it follows, that this implement is drawn with the least possible waste of power. 2 From the curved form of the tines, all stubble, couch, &c that the tines may encounter in their progress through the soil, is brought to the surface, and rolled up to the face of the tines; when it loses its hold, and is thrown off (*at b b b b*) always relieving itself from being choked, however wet or foul the land. 3. The mode by which this harrow can be so easily adjusted to work at any depth required, renders it of great value this is done as quick as thought by moving the regulator (*c*) upwards or downwards between the lateral spring (*d e*) and by each movement upwards into the opening (*f g h i k*), the fore tines (*l l l l*) will be allowed to enter the soil about an inch and a half deeper by each movement into the different spaces, until the regulator is thrown up to (*n*), when the harrow is given its greatest power, and will then be working at the depth of eight or nine inches. Also the axle-tree of the hind wheels is moved betwixt *o* and *p*, a space of

seven or eight inches, by a screw through the arbutree, which is turned by a small handle (g); so that the hind part of the harrow, by this simple mode, is also regulated to the depth at which it is found necessary to work. 4 When the harrow is drawn to the head or foot lands, the regulator is pressed down to d, and the fore wheel (n) is then allowed to pass under the fore bar (a), by which the nose of the harrow is lifted, and the points of the fore tines (lill) will then be taken two or three inches out of the soil, which affords the means of turning the harrow with the greatest facility. 5. Being made of malleable iron, its durability may be said to be endless, whereas, if made of wood, the prime cost would be entirely lost at the end of every five or six years. Lastly the mode of working is so easy that any boy of ten or twelve years of age is perfectly qualified to manage it. Next to Wilkie's brake, we consider this the most valuable of pronged implements, and think that, like Wilkie's implement, it might be substituted for the plough, after drilled green or root crops, on light soils generally. Some account of the astonishing powers of the implement, as exemplified in breaking up Hyde Park, London, in 1826, will be found in the *Gardener's Magazine*, vol. ii p. 250.

3658. *Wolfe's improved cultivator* (fig 325.) is a very effective implement of this kind,

with nine coulters or prongs. It may be set to go more or less deep by raising or lowering both the fore and hind wheels.

3659. The *Scotch cultivator or grubber* (fig 326) was formerly considered one of the best implements of this kind, as a substitute for the plough, but it has since been superseded by Finlayson's self-cleaning harrow. It consists of two strong rectangular frames, the one including the other and nine bars mortised into the inner one, with eleven coulters or prongs with triangular sharp-edged, chipping feet, four cast-iron wheels, and two handles. All the cutters are fixed in these bars, except two which are placed in the side beams of the outer frame, and may be set to go more or less deep by means of pins and wedges. It works as deep as the plough has gone, and by the reclined position of the coulters, brings to the surface

all the weed roots that lurk in the soil. Beans and peas have been sown in spring on the winter furrow after being stirred by the grubber and barley also after turnips, without any ploughing at all. This implement is made of different sizes, and may be worked either by four or by two horses, and one man.

3660. *Forthmann's cultivator* (fig 327) has been found a very useful implement, both for stirring and cleaning land. Its inventor recommends that

where the land is foul from couch, sedge, or any other cause, the number of teeth or hoes should be reduced to five or seven; two or three being placed in the fore pull, and four in the hindermost; increasing them to nine as the land becomes in a fine condition.

2661. The chain by which this cultivator or scarifier is drawn, enables the person that holds it to work it better, than if it were drawn by a beam like a plough, and occasions also less draught by the power being nearer to the claws the machine goes more freely than it would if some of the claws were in the fore bull, the sole use of that bull being to draw by. When the scarifier was made in a triangular form, and with the same number of claws, it was apt to go on its head, or by raising the hindmost claws out of the ground to work frequently at one corner only. The claws are formed at the bottom with a point, so as to push a stone out of the way before the broad part can meet with any obstruction, which makes the machine cut with much greater ease. As to their width at the foot, they may be made to cut all the land more clearly than a plough if required, where thistles, fern, &c. grow, and the claw is so formed by its crooked direction as to raise every obstruction to the top, rock excepted.

2662. *Hayward's cultivator* (fig 928) or, as it is called, extirpator, or scalp plough, is used on land already ploughed. Its hoes or scalp are intended to pierce about two inches at each operation, so that by repeatedly passing it over the surface, the land will be stirred as deep as the plough has gone.

2663. *Beaton's cultivator* (fig 929) is recommended by the inventor for its lightness it is intended, as before observed (2650.), to effect by reiterated application what is done by the large Scotch cultivator at once by which means a saving of power is obtained, but with a loss of time, as is usual in all similar cases.

2664. The only essential tillage implement of the prong kind is Wilkie's brake, which, taking it altogether we consider to be one of the most perfect implements ever invented. The next is Finlayson's harrow also a most excellent implement. The other cultivators and brakes are so far inferior, that they may be considered as reduced to historical merit and we have therefore retained them chiefly for the purpose of showing the progress which has been made in this department of agricultural mechanism.

#### SUBJECT 4. Tillage Implements of the Hoe Kind.

2665 Of horse hoes there is a great variety, almost every implement-maker having his favourite form. They are useful for stirring the soil in the intervals between rowed crops, especially turnips, potatoes, and beans. Respecting the construction of horse hoes it may be observed that soils of different textures will require to be hoed with shares of different forms, according to their hardness, or mixture of stones, flints, or gravel. The number of hoes also in hard soils requires to be diminished in the case of a stony clay one hoe or flat share, with or without one or two coulters or prongs, will often be all that can be made to enter the ground. In using these implements the operator should always consider whether he will produce most benefit by merely cutting over or rooting up the weeds, or by stirring the soil, because the hoe suited for the one purpose is by no means well adapted for the other. In the former case flat shares are to be preferred, but pointed, that they may enter the soil easily in the latter, coulters or prongs, as in the cultivators, are much more effective, as they will enter the soil and stir it to a considerable depth, thus greatly benefiting the plants by the admission of air, heat, dew, and rain, and by rendering it more permeable by the roots.

2666. *Wilkie's horse hoe and drill harrow* (fig 330.) is a very superior implement, intended to be introduced between the drills as soon as the plants appear above ground,

830

D d J

and the operation is repeated at intervals till the crop is thoroughly cleaned. The centre hoe is stationary, and the right and left expand and contract in the same manner as in the horse hoe. The depth is regulated by the wheel at the point of the beam, and may be varied from one to six inches. The hoes cut the bottom of the space between the drills completely, while the harrow following, pulverizes the soil, and takes out the weeds. Should circumstances require, the wings of the harrow may be taken off, and the hoes only used, or the hoes displaced, and the harrow only employed. This implement was invented by the late Mr Wilkie of Uddington, near Glasgow, in 1820, and is the first instance of the cycloid form being adopted in hoes or prongs. Afterwards Mr Finlayson applied this form to his harrow; and subsequently Mr Wilkie, junior, of Uddington, to his admirable brake (3655.)

3667. *Finlayson's self-cleaning horse hoe and drill harrow* (fig. 331) is an excellent

331

implement, and as a harrow is preferable to that of Wilkie (3665), from whose implement it differs chiefly in being more a harrow than a hoe, and in every prong being calculated for cleaning itself.

3668. *Wilkie's horse hoe and drill plough* is considered an effective implement. The mould-boards are taken off when used as a horse hoe, and the hoes taken off and the mould-boards replaced when earthing up the crops; thus combining, in one implement, a complete horse hoe and double mould-board plough. A good horse hoe being the principal object in the construction of this implement, the method of fixing the hoes demanded particular attention, in order to combine lightness with strength and firmness, and admit, at the same time, of being set at different degrees of width and depth, all of which are accomplished on an improved principle. The wheel at the point of the beam regulates the depth; the right and left hoes are hinged, at the back end, to the handles of the plough, while by moving on the circular cross bar on which they are fastened with wedges, they may be set to any width, from about twelve to nearly twenty four inches.

3669. *Webb's expanding horse hoe* bears a considerable resemblance to Wilkie's implement. It has circular coulters, hoe-tines, and a double mould-board. When used for earthing up potatoes, the mould-boards and coulters are put on; when used as a hoe, the curved coulters are put in the expanding bar according to the width between the rows.

3670. *Blakie's inverted horse hoe* (fig. 332.) consists of a line of coulters set in a beam,

and this beam attached to the axle of a pair of common wheels. It hoes several rows at once, and instead of being straight the coulters are all curved or kneed, and set back to back so as to include a row between each pair. The advantage of the kneed or bent form of the lower part of the coulters is, that the soil is pared off in a sloping direction from the plants, which are thus not so liable to be choked up with earth, as by a broad hoe

or share; or to have their roots so much exposed to the air as by cutting perpendicularly down close to the row, by a common coulters. It is chiefly adapted for drilled corn, and then it works several rows; in turneps it may work one or two according to the soil; in all cases where the width between the rows admits, the agriculturist should be more anxious

332

to stir the soil to a good depth then to skin over a great extent of surface, merely cutting over the weeds.

2671. The Scotch horse hoe (fig. 333.) has three hoes or shares, and is drawn by a single horse. By means of the wheel it can be set to go to any depth and in hard surfaces, one share or more can be taken out, and coulters or bent prongs, as in the cultivator (fig. 325.), substituted.

2672. The Northumberland horse hoe (see Report, fig. p. 43.) is of a triangular form, and contains three coulters and three hoes, or six hoes, according to the state of the soil.

In hoeing between drills of turneps, the two side coulters are used of a curved form. A hoe of the same kind is sometimes attached to a small roller, and employed between rows of wheat and barley, from nine to twelve inches distant.

It is also used in place of a cultivator in preparing bean-stubbles for wheat in autumn, and in pulverising lands for barley in spring.

2673. Henry's improved scryfler (fig. 334.) is a strong light implement, which may be set to any width, and its foot soles will be found effective.

2674. Ames's expanding horse hoe and harrow (fig. 335) is said to be much used in Lincolnshire. The hoe is constructed with expanding shares (a a), which can be

333

334

335

336

set to different distances, as it may be required, within the limits of twelve and thirty inches. The harrow which is attached to it is found advantageous in clearing lands from successive crops of weeds, as well as in bringing them to a proper state for the purpose of cropping; serving in this respect as a cultivator.

2675. The hoe and castor wheel (fig. 336) is said to enable the holder to guide the shares more correctly between narrow rows of corn drilled on a flat surface. It is not often required, and must be unnecessary if the rows have been correctly sown.

3676. *The double hoe or hoe scythe* (fig. 367) is an invention by Amos. "It is used," he says, "for the purpose of cutting over thistles, and other injurious weeds in pasture lands. In the execution of the work it not only greatly reduces the expense, but executes it in a much easier manner than the common scythe. One man and a horse are said to be capable of cutting over twenty acres in a day." The leading share (a) is made of cast steel, in the form of an isosceles triangle, whose equal sides are fourteen inches long, and its base twelve inches, it is about one eighth of an inch thick in the middle, tapering to a very fine edge on the outside, and the scythes (b b b) are fixed to four pieces of ash wood, three inches square, and two feet four inches long. These scythes are three feet long from point to point, four inches broad at the widest part, and made of cast steel. The agriculture where such a machine as this is wanted, must surely be of a very rude and imperfect kind; for even supposing the machine to cut over the thistles, that operation cannot be so effectual as cutting them under the collar by hand with the spade or spud.

2677. *The only essential implements of this class are those of Wilkie and Finlayson.*

#### SECT. II. *Machines for Sowing and Planting*

2678. *Machines for sowing or planting in rows* are very various, and often too complicated. Harte says, the first drill machine was invented by a German, and presented to the court of Spain in 1647 but it appears, from a communication to the Board of Agriculture, that a sort of rude drill or drill plough has been in use in India from time immemorial. Their use is to deposit the seed in equidistant rows, on a flat surface on the top of a narrow ridge in the interval between two ridges or in the bottom of a common furrow. Corn when drilled, is usually sown in the first of these ways, turnips in the second; and peas and beans in the third and fourth. The practice of drilling corn does not, however, seem to be gaining ground; and even where it is found of advantage to have the plants rise in parallel rows, this is sometimes done by means of what is called ribbing, a process more convenient in many cases than sowing with a drilling machine.

2679. *Of corn drills*, Cooke's improved drill and horse hoe (fig. 338), though not the most fashionable, is one of the most useful implements of this kind on light dry soils, on even surfaces, and in dry climates. It has been much used in Norfolk and Suffolk, and many other parts of England. The advantages of this machine are said to consist,—1. In the wheels being so large that the machine can travel on any road without trouble or danger of breaking also from the farm to the field, &c. without taking to pieces. 2. In the coulters-beam (a), with all the coulters moving with great ease, on the principle of the pentagraph, to the right or left, so as to counteract the irregularity of the horse draught, by which means the drills may be made straight and, where lands or ridges are made four and a half, or five and a half feet wide, the horse may always go in the furrow, without setting a foot on the land, either in drilling or horse hoeing. 3. In the seed supplying itself regularly, without any attention, from the upper to the lower boxes, as it is distributed. 4. In lifting the pin on the coulters-beam to a hook on the axle of the wheels, by which means the coulters are kept out of the ground, at the end of the land, without the least labour or fatigue to the person who attends the machine. 5. In going up or down steep hills, in the seed-box being elevated or depressed accordingly, so as to render the distribution of the seed regular; and the seed being

covered by a lid, and thus screened from wind or rain. The same machine is easily transformed into a cultivator, horse hoe (fig. 339.), scarifier, or grubber, all which

339

operations it performs exceedingly well and by substituting a corn-rake, stubble-rake, or grass-rake, for the beam of coulter, or hoe (a), it will rake corn-stubbles, or clean lands of root weeds. When corn is to be sown in rows, and the intervals hoed or stirred, we scarcely know a machine superior to this one and from being long in a course of manufacture, few can be made so cheap. But these advantages, though considerable in the process of drilling, are nothing when compared with those which arise from the use of the horse hoe with which from eight to ten acres of land may be hoed in one day with one man a boy, and one horse, at a trifling expense, in a style

far superior to, and more effectual than any hand-hoeing whatever, also at times and seasons when it is impossible for the hand-hoe to be used at all

2680. The *Norfolk drill*, or improved lever drill (fig. 340.), is a coffin drill on a larger scale than Cooke's, as it sows a breadth of nine feet at once it is chiefly used in the light soils of Norfolk and Suffolk as being more expeditious than Cooke's, but it also costs about double the sum.

340

2681 Cooke's three-row corn drill is the large machine in a diminutive form, and is exceedingly convenient for small demesne farms where great neatness is attended to. It can be used as a cultivator, hoe, rake, &c like the other

2682 *Murton's improved grain drill-machine* (fig. 341.) is decidedly the simplest and

341

best of corn drills. In this machine three hoppers are included in one box, the seed escaping out of all the three by the revolution of three seed cylinders upon one axle; and drills of different breadths are produced simply by the shifting of a nut, that fixes a screw moving in a

groove in the under-frame, by which the distance between the two outside conductors and

but equal one (which is fixed) can be varied from nine to ten or eleven inches; and that the four small wheels may always be at the same distances respectively as the conductors, there are two washers (hollow cylinders), an inch in breadth, on the axle-arms of each, which may be transferred either to the outside or inside of the wheels, so as to make their distances from the outside conductors nine, ten, or eleven inches respectively also. The small wheels may be raised or depressed, so as to alter the depth at which the seed shall be deposited, by the action of a wedge, which retains the upright part of the axle in any one of a number of notches, which are made similarly in both, and which are caught by an iron plate on the upper side of the arms which carry the axles. This machine may be still further improved by increasing the number of conductors to five instead of three, the latter number giving too light work to the horses. (*Highland Soc. Trans. vol. vii.*)

2683. Of bean drills there are three kinds, all equally good one for sowing in prepared drills or after the plough, which is pushed by manual labour, and has been already described (2574.) one attached to a light plough, which draws a furrow in prepared soil,

and sows a row at the same time (*fig. 342.*); and one which can be fixed between the handles of any common plough for the same purpose. The former has a wheel (a) to regulate the depth of the furrow, and a lever (b) to throw the drill out of gear on turning at the ends of the ridges. It is a useful and very effective implement though a skilful ploughman will effect the same object by a

drill placed between the handles of a common swing plough.

2684. *Wor's expanding bean drill to sow four rows* is affixed to a pair of wheels and axle, in the manner of Cooke's drill. The axle which passes through the drill boxes has four movable brushes and cylinders, by which means any width, wider than that of the axle can be given. Where ground is prepared and ribbed, and where there is not a Cooke's drill on the premises, this machine may be resorted to with convenience.

2685. *The block-plough drill* is an equilateral triangular block, 50 inches to a side, with cast-iron scutcher teeth and wooden blocks shipped over them. A field being ribbed or laid up in ridges with this implement, is next sown broadcast with wheat and bush-harrowed, by which the grain rises in rows, as accurately as if sown with the drill (*Form. Mag. vol. xiii. p. 406.*)

2686. *Machines for dibbling beans*, impelled by manual labour, have been already noticed (2574.). A horse dibbling machine (*fig. 343.*) has been invented, though very little used,

and being rather complicated in its movements, it will require considerable simplification before it can be recommended. A heavy cast-iron roller, with protruding angular rings, might form drills for the beans, and, probably, some machine of this sort might distribute them singly or nearly so, and at regular distances: but the best cultivators prefer sowing in drills, more thickly than in dibbling, in order to admit of a wide interval for

culture, so as not only to clean the surface as between dibbled rows, but to stir and work the soil, and produce a sort of semi-fallow

2687 *Of turnip drills*, the best, when this root is cultivated on a large scale, is the improved Northumberland drill. (*fig. 344.*) The roller (*a*) which goes before the seed has two concavities, and thus leaves the two ridgelines in the very best form for the seed; after these are sown, two light rollers (*b b*) follow and cover them. It is drawn by one horse, sows two rows at once, and seldom goes out of repair.

2688. *Common's (sometimes French's) sowing drill* (*fig. 345*) is generally considered one of the best. Common was a cartwright at Denwick near Alnwick, and received a medal from the Society of Arts, and twenty guineas from the Highland Society, for his invention, in 1818. He made the machine of wood but iron being found so much more suitable and durable, the manufacture of Common's drills fell into the hands of blacksmiths, and chiefly of French of Alnwick from which circumstance it is frequently known by that maker's name. The machine is easily put in and out of gear by means of a lever (*a*), and since it has hoppers (*b b*) have been added for that purpose. The seed and manure, when deposited in the gutter traced by the coulters (*a c*) are covered by two small flat rollers, as in the common Northumberland drill. Common's machine is not yet perfect: the seed is not measured out with sufficient accuracy and it stands too high from the ground, gets top heavy and on hill sides does not sow the seed in the middle of the drill furrow. It is best made with two wheels, which steadies it in all situations: the funnels being still attached to the guards of the concave shafting rollers, deposit the seed with much more neatness and accuracy (*J. G. R. near Alnwick*.)

becomes the fashion to sow pulverized manure with turnip seed, two

has two wheels which run in the hollows on each side of the drill or ridgeline to be sown,

2689 *The Northumberland one-row turnip drill* (*fig. 346.*) the drill or ridgeline to be sown, by which means the sower is enabled to keep the row exactly in the centre of the drill. The ridgelines are previously rolled, either by a common or concave roller, the latter being preferable and as the horse goes in the furrow at one side of the drill to be sown, of course he draws from one side of the draught-bar of the barrow. A small roller follows, and covers and presses in the seed. A recent improvement in this machine

is the addition of a hopper (*a*) for pulverized manure, over which a barrel of water might easily be suspended, if deemed requisite.

2690. *Weir's manuring one-row turnip drill* (*fig. 347*) is a remarkable improvement on the Northumberland implement. It has a manure hopper (*a*) and a seed hopper (*b*), the same as the other; but the manure, in place of being dropped along with the seed,

is deposited in a deep gutter made by a coultter (c) which goes before; this manure is covered by a pronged coultter (d) which follows the other; next comes the coultter

which forms the gutter for the seed (e). The seed is thus deposited about one inch above the manure. One roller of the concave kind goes before the machine, and another light one of the common kind follows after it or, without attached rollers, the drill may be affixed to one side of the common roller behind, which roller may prepare one drill and cover the seed sown on another each course.

2691. The *drill roller* is so contrived as to form regular small incisions or drills in the ground, at proper depths for the seed. It is merely a common roller, mostly of iron, about seven feet long, about which are put cutting-wheels of cast iron, that turn round the common cylinder, each independently of the others, which cylinder generally weighs about a ton. It is drawn by three or four horses abreast, and driven by a man elevated behind them; the cutting-wheels, being movable, may be fixed at any distance, by means of washers but the most common and favourite distance is four to six inches. It is said to have been found effectually productive of the principal benefits which have been derived from the operation of drill ploughs, or the practice of dibbling and setting the corn by hand, with the great advantage of saving both time and expense as by the use of this simple machine, one man may sow and cover five or six acres of corn in one day, using for the purpose three horses, on account of its weight. It was at first chiefly used on clover or other grass leys on the first ploughing, but may be as properly employed on land which has been three or four times ploughed. The mode of working it is thus — "A clover ley or other ground being ploughed, which the cultivator intends for setting or dibbling with wheat, the roller is drawn across the furrows, and cuts the whole field into little drills, four inches asunder the seed is then sown broadcast in the common quantity, and the land bush-harrowed by which means the seed is deposited at one equal depth, as in drilling, and that depth a better one than in setting, and the crop rises free from the furrow-scams, which are the ill effects of common broadcast sowing, at least on a ley ploughed once." To us this machine, so much praised by some writers, seems merely an ingenious mode of increasing the expenses of culture. By the use of a plough, such as Small's, that will cut a square furrow no machine of this sort can possibly become necessary. The land when ploughed will be left in little drills, and being sown broadcast, the seed will come up as if it had been drill rolled or ribbed. It is admitted, however, that the pressure of the roller may be useful in soft lands, and may, possibly, keep down the wire-worm. For this purpose we have the *pressing plough*. (3713.)

2692. The *drill-watering machine* (fig. 345.) is an implement of recent invention by John Young, a surgeon, in Edinburgh. It is used for watering turnips and other drill crops in dry seasons; and promises to be a valuable assistant to the amateur agriculturist, in dry seasons or situations, or where it is an important subject to secure a crop. It has been much approved of by the Highland Society of Scotland and the Dukes of

*Farmers Society. (See Farm. Mag. vol. xxi. p. 1.)* The machine consists of a barrel, which is mounted upon a cart frame, and discharges water from a ball stop-cock having

four mouths (a) communicating by means of a leathern hose with four horizontal tubes (b b b b) shut up at the end by a screw (c), which admits of the tube being cleaned. The tubes are placed parallel with the drills, two between the wheels of the cart, and one on the outside of each wheel the distance of the tubes, and their height from the surface are regulated by hooks and chains and the water is discharged in small streams, through twenty projecting apertures in the under part of the tubes. The tubes are suspended by chains to the hooks in an iron rod secured to the fore and back part of the frame of the cart. The mouth of the funnel on the top of the barrel is covered with a wire-cloth to prevent any thing getting in to clog the apertures. The quantity of water let out by the apertures being less than what is received into the tubes, the tubes are always full by which a regular discharge is kept up from all the apertures at the same time. As the machine advances, the stream which falls from the first aperture upon the plants is followed up by successive streams from all the apertures in the tube, therefore each plant must receive the discharge from twenty apertures.

2693 *Estimate of its operation.*—Supposing the barrel to contain 900 gallons, and the tubes to be five feet long, the diameter of the tubes three eighths of an inch and the diameter of the aperture in the tubes one sixteenth of an inch 900 gallons will be discharged from 80 such apertures in two hours one third. The diameter of the mouths of the stop-cock must be equal to the diameter of the tubes. The horse going at the rate of 2½ miles in one hour in two hours and twenty minutes will go 5 miles five sixths. The distance between four drills is 6 feet 9 inches therefore if we suppose a parallelogram to be 6 feet 9 inches broad, and 5 miles five sixths long the area of this parallelogram will be 4 acres 3 roods 16 perches, which will be watered by 900 gallons in two hours and twenty minutes and in one hour will be watered 2 acres 7½ perches supposing the water to flow uniformly but the quantity given out upon the drills must be regulated by the progressive movement of the machine.

2694. *In construction* it is neither complicated nor expensive it may be erected upon the frame of a cart used for other purposes in husbandry and the barrel and apparatus may be furnished for about six pounds sterling, supposing the stop-cock and connecting screws to be made of brass, and the tubes of copper or tin. This machine may be used for other purposes such as the application of urine as a manure or of a solution of muriate of soda, which has been proposed for some crops.

2695 The best drill machines are French's and Welch's for turnips, Marton's for corn, and the drill attached to a plough (3686) for beans.

SECT. III. *Harrows or Pronged Implements for scratching the Surface Soil, for covering the Seed, and for other purposes*

2696 The harrow is an implement of equal antiquity with the plough and has of late years undergone so much improvement as to have originated that class of pronged implements known as cultivators, grubbers, &c. The original uses of the harrow seem to have been chiefly three that of reducing or comminuting soil already stirred or ploughed tearing root weeds out of such soil and covering sown seeds. We shall confine ourselves in this section to these three uses.

For the purpose of stirring the soil to the depth of eight or ten inches and tearing up weeds, no harrow is preferable to that of Finlayson, or Wilkie, in which the tines or prongs are of the cycloidal form. For the purpose of breaking and pulverizing the surface of soils, straight prongs, and such as present by breadth or position greater resistance when drawn through the soil, are preferred. It is generally considered that prongs whose horizontal section, a few inches above the point, is a square or a parallelogram (fig. 349.) are best adapted for the attrition to which they are subject in being moved forward in a direction parallel to their

diagonals, and for resisting the lateral or shaking motion occasioned by encountering stones. (*Quart. Jour. Agr.* vol. II. p. 555.) The principal parts of harrows are generally made of wood; but they are frequently also constructed entirely of iron.

3507. The *Berwickshire harrow* (fig. 350.) is the most perfect implement of the kind in general use. It consists of two parts joined together by iron rods, having haps and hooks. Each part consists of four bars of wood technically termed *bulls*, and connected together by an equal number of cross bars of smaller dimensions mortised through them. The former of these bars may be 2½ inches in width by 3 inches in depth, and the latter 2 inches in width by 1 inch in depth. The longer bars are inclined at a certain angle to the smaller, so as to form the figure of a rhomboid, and they have inserted into them the teeth at equal distances from each other. This inclination of the longer bars is made to be such, that perpendiculars from each of the teeth, falling upon a line

drawn at right angles to the line of the harrow's motion, shall divide the space between each bar into equal parts, so that the various teeth, when the instrument is moved forward, shall equally indent the surface of the ground over which they pass. (*Quart. Jour. Agr.*)

3508. The *angular-sided hinged harrow* (fig. 351) is one of the best implements of

the kind, as it both operates on the ground with great regularity and is less liable to ride or be deranged in turning, than the common, or the rhomboidal harrow.

3509. The *grass seed rhomboidal harrow* (fig. 352.), is nothing more than the Berwickshire harrow on a smaller scale. It is used chiefly for harrowing in clover and grass seeds when sown among corn crops, or even alone.

3700. The *common brake* (fig. 353.) is merely a harrow of the common kind, of

greater weight and dimensions than necessary for ordinary soils. Its use is to reduce the stronger clays, at a time when they are too obdurate to be impressed with the teeth of the common harrow. The levelling brake, or grubber, is generally considered the preferable implement for this purpose.

2701. The brake, grubber, or levelling harrow (fig. 354.), is a valuable implement on strong clayey soils. It consists of two frames, the one triangular and the other oblong. By means of the handles, the oblong part of this brake can either be raised up or depressed; so that when the ground is cut in small pieces by the teeth of the triangular harrow, then the oblong harrow following, its teeth being pressed down into the high parts, carry or drag part of the soil off from the heights; and, when they are raised up by the handles, leave that soil in the hollow or low parts. By this means, the ground is brought nearly to one plain surface, whether that surface be horizontal or sloping. Sometimes it may be found necessary to place a greater number of teeth in the oblong part of the brake, so that they may be nearer to one another, and perform the operation more effectually. The teeth are made sharp or thin on the fore edge, for cutting broad and thick on the back, for strength and tapering, from a little below the bulls to their joints.

2702. Morton's revolving brake harrow (fig. 355.) is a very powerful implement in strong clayey soils infested with couch. When the implement is to be moved from one field to another, the large wheels may be brought forward (a) to support the tines from the ground, while the hind axle and the rake are supported by a castor or truck-

wheel (b). In most soils, four horses and a driver and holder are necessary to work this instrument, which, however, no good farmer will ever require the aid of unless it be when entering upon land which has been allowed to run wild, or clay of an extraordinary degree of tenacity. We have seen it extensively and advantageously used, on the latter description of soil, by Mr. Jackson of Kildbrook farm, Blackheath, Surrey (*Gerd. Mag.* vol. iv. p. 186).

2703. As substitutes for the last two implements, may be mentioned Finlayson's harrow (3657), Wilkie's brake (3656.), and Kirkwood's improved grubber, which will be afterwards figured and described, the invention being only made public while the present sheet is passing through the press (February 15.). Bardett's cultivator, Brown's cross-cutting machine, the Sythney scarifier, and the spiky roller, noticed in next section, are used for a part of the purposes of the last two implements.

356. *Fig. 356. Heavy cast-iron harrow for hot weather (Fig. 356.)*

promotes to be useful in certain situations, as in a tenacious retentive soil and moist climate. The sowing of wheat, under existing circumstances, is one of the most important branches of the corn farmer's labour. In some backward seasons, it is almost impossible to get wheat land harrowed according to the common method, especially land that has been reduced by summer fallow, without subjecting it to poaching from the horses, which is not only unfavourable to the soil, but also occasions a great waste of seed. Hence it often happens, that a less quantity of grain is got sown than was intended, or is

requests for the supply of the market. The beam (a) to which the harrows are attached admits of being made shorter or longer as the width of the ridge requires. The shafts have freedom to turn round either to the right hand or to the left, and the teeth of the harrows are placed square in the bull, so that they can be drawn from either end at pleasure. The wheels (Fig. 357) may be from three to four feet in diameter if made on purpose but for the professional farmer it will be sufficient to borrow a pair from a one-horse cart.

3705. The bush harrow (Fig. 358.) is used for harrowing grass lands to disperse roughness and decaying matter, and it is also sometimes used for covering grass or clover seeds. Small rigid branches of spray are interwoven in a frame, consisting of

three or more cross bars, fixed into two end-pieces in such a manner as to be very rough and bushy underneath. To the extremities of the frame before are sometimes attached two wheels, about twelve inches in diameter, upon which it moves sometimes, however, wheels are not employed, but the whole rough surface is applied to, and dragged on, the ground.

3706 The only essential implement of the harrow kind is the Berwickshire harrow (Fig. 360.)

#### SECT. IV. Rollers.

3707 The roller is constructed of wood, stone, or cast iron, according to convenience or the purposes for which it is to be used. For tillage lands, the roller is used to break the lumps of earth, and in some cases to press in and firm the ground about newly sown seed; on grass lands it is used to compress and smooth the surface, and render it better adapted for mowing. It has been matter of dispute whether rollers with large or small diameters have the advantage in point of effect upon the land. In constructing heavy rollers, they should not have too great a diameter whatever the material be of which they are formed, as the pressure is diminished where the implement is of very large size, by its resting on too much surface at once, except an addition of weight in proportion be made. By having the roller made small, when loaded to the same weight, a much greater effect will be produced, and a considerable saving of expense be made in the construction of the implement. The common length of rollers is five or six feet, and the ordinary diameter from fifteen to thirty inches, but those employed for flattening

one-horse shaft, in order to prepare them for drilling carriages upon, are commonly shored and of much less diameter. Large rollers should have double shafts, in order that they may be drawn by two horses abreast; and such as are employed for unstable lands should have a scraper attached to them. Strong frames are also necessary for rollers, so that

proper weights may be put upon them; and open boxes or carts (fig. 359) placed upon them may sometimes be requisite, in order to contain any additional weight that may be thought proper, as well as to receive stones or other matters that may be picked up from the ground. Pieces of wood or stone, as

heavy as a man can lift, are the most suitable substances for loading these implements with, where they have not the advantage of boxes for receiving loads.

3708. The *parted cast-iron roller* was invented to remedy the inconvenience experienced in the use of the common implement, in turning at the ends of ridges or other places, where, from the roller not moving upon its axis, but being drawn along the surface of the ground, it is liable to bear it up, and make depressions before the cylinder comes again into the direct line of draught, and at the same time it is not brought round without great exertion in the teams. The cylinder, in two pieces (fig. 362. a & c), obviates this inconvenience, by enabling the two parts to turn round on their own axis, the one forward, and the other in a retrograde direction.

3709. The *spiky or compound roller* is occasionally employed in working fallows, or preparing stiff bean-land for wheat. In stiff clay-ground, when ploughed dry, or which has been much trod upon the furrow-slices will rise in large lumps, or hard clods, which the harrow cannot break so as to cover the seed in a proper manner. In this state of the ground, the rollers commonly used have little effect in breaking these hard clods. Indeed, the seed is often buried in the ground, by the clods being pressed down upon it by the weight of the roller. To remedy this, the spike-roller has been employed, and found very useful but a roller can be made, which, perhaps, may answer the purpose better than the spike one. This roller is formed from a piece of hard wood, of a cylindrical form on which are placed several rows of sharp-pointed darts, made either of forged iron, or cast metal. These darts, by striking the hard clods in a sloping direction, cut or spit them into small pieces and, by this means, they must be more easily pulverised by the harrow.

3710. *Bartlett's cultivator* (figs. 360 and 361) is an implement of the roller kind,

360

said to be useful in preparing wet land for tillage in Cornwall. It consists of a roller composed of 13 thin iron plates, each fastened to a circular block of wood of four

inches in thickness, and nine inches in diameter, and bound round with iron. Both blocks (a) and plates (b) are movable on an iron axle; and though Mr Bartlett, the inventor, has adopted a diameter of nine inches for the blocks, and fifteen inches for the plates, yet these dimensions may be increased or diminished at pleasure. The frame in which the roller is inserted has a bar, on which are fixed scrapers of iron, which keep the roller continually clean (*Gard. Mag.* vol. v.)

3711 The roller and water bar (fig. 362) is sometimes used for watering spring

E c

straps, or cleaves, with liquid manure, previously rolling them. It has the advantage of

362

a more perfect machine, in the holes being easily cleaned when choked up with the thickened water

363

2712. The *furrow-roller* (fig. 363.) is contrived for the purpose of rolling the furrows in steep hilly situations, and other places where the common roller cannot be employed.

2713. The *Norfolk drill-roller*, and the *ridge and furrow concave or scalloped roller* attached to certain turnip-drills, have already been depicted.

(3680. and 3689.)

2714. The *pressing plough* is a term erroneously applied to a machine of the roller

364

kind (fig. 364.) It generally consists of two cast-iron wheels, for the purpose of impressing two small seed gutters or drills on the furrow slices turned over by the common plough, and a third wheel for running in the bottom of the furrow

for the purpose of keeping the machine steady. The wheels are kept clean by scrapers. (fig. 365.) This implement is used in breaking up clover leys for wheat: two ploughs follow each other and after them one horse, walking in the furrow, drags the pressing plough. The advantages are said to be a firm bed for the seed, by which it is not liable to be thrown out in the winter season, and not so liable to be attacked by the grub and wire worm, and the rising of the plants in rows, by which means they may be hoed or harrowed between.

365

2715. Brown's *cross-cutting machine* (fig. 366) is used for cross-cutting the furrows

366

of rough, mossy, and heathy land, in order to reduce the soil to a state fit for receiving the seed. It consists of a series of parallel iron plates, or blades as they may be termed, fixed in a frame-work of wood, by the weight of which, and the pressure on the shafts by the driver, they are forced into the ground. The frame consists of oak; and the main beams are 4 feet long, 6 inches deep, and 5 inches broad, with cross bars of proportional strength. The handles are 6½ feet long. The blades are of good foreign iron, 4 feet 3 inches

long,  $3\frac{1}{2}$  inches broad, and five eighths of an inch thick at the back. The curves of the blades are formed to a circle of 40 inches diameter (*Engl. Soc. Trans.* vol. vii.)

2716. *The Siskney scarifier, or hark*, consists of a cylinder with many circular cutters, or a number of circular cutters connected together upon one axis, which is intended to pass over the ground, for the purpose of scarifying or cutting the surface of grass land, perpendicularly, to the depth of a few inches, and to any required degree of fineness. By means of this scarifier, or hark, the roots of old grass may be effectually destroyed without the labour of ploughing, which is calculated to enable the farmer to graze the land much longer, previously to breaking it up for wheat or turnip tillage. The apparatus is proposed to be connected to the hinder part of an ordinary cart or the axis of the cylinder, or circular cutters, may be supported by two iron arms, attached to the axletree with a pair of common carriage wheels. When this machine is used for renewing lawns or grass land, it will then be necessary to fix above the cutters a box containing grass seed, which box must be perforated with small holes, one hole being exactly over every cutter, so that the seed may fall immediately into the furrow produced by the cutter (*Newton's Journal*, vol. i. p. 250.)

2717. *The only essential roller for general purposes* is the parted cast-iron roller, with a scraper and box over (*fig. 359.*).

#### SECT. V. *Machines for laying Land even, and other occasional or anomalous Tillage Machines.*

2718. *Various machines* for agricultural purposes are occasionally brought into notice by amateur cultivators, and some even by the professional farmer. It forms, indeed, the privilege and the characteristic of wealth and intelligence, to procure to be made whatever particular circumstances may require, in every department of the mechanical agents of culture. We shall only notice a few, and that chiefly for the purpose of showing the resources of the present age.

2719. *Of machines for laying land level* two may be noticed: in the first and best

(*fig. 367*) the horses are harnessed to a pole (*a*), which is joined to an axle having a pair of low wheels (*b c*). Into this axletree are mortised two long side-pieces (*d*) terminating in handles (*e e*). Somewhat inclined to these long or upper side pieces shorter lower ones are joined by cross pieces, and connected by strong side-boards. The machine has no bottom its back part (*f*) is strongly attached to an axle (*fig. 368 g*), and to the bottom of this the scraper part (*h*) is firmly screwed. The front ends of the slide irons (*fig. 367 m*), turning up, pass easily through mortises in the upper side-pieces (*d*), where, by means of pins, the inclination of the slide irons and of the back board can be adjusted within narrow limits, according to the nature of the soil to be levelled and the mass of earth previously loosened by ploughing. This earth the back board is intended to collect and force before it, until the machine arrives at the place where it is intended to be deposited. Here, by lifting up the hinder part of the machine by its handles (*e e*), the contents are left on the ground, and the machine proceeds to a fresh bullock. (*Suppl. Encycl. Brit.* i. 25.)

2720. *The Flemish levelling machine* (*fig. 369.*) may be considered as a shovel, on a large scale, to be drawn by a pair of horses; it collects earth at the pleasure of the holder, who contrives to make the horses turn over the shovel and empty the contents, by merely letting go the handle (*a*), and recovering it by

means of a cord (*b*), when emptied, as already described. (*AGS.*)

2721. *The levelling harrow* (*2701*) is adequate to all ordinary purposes.

*SECT. VI. Machines for reaping and gathering the Crops.*

3722. The *horse machines* of haytime and harvest are chiefly the horse rakes, the hay tedder, and the raking machine.

*SUMMARY. 1 Horse Rakes and Haymaking Machines.*

3723. Raking machines are not in very general use but, where corn is mown, they are successfully employed in drawing together the scattered stalks, and are also of great use in haymaking. The saving in both cases consists in the substitution of animal for manual labour.

3794. The *common or Norfolk horse rake* (fig. 370.) is employed for barley and oat crops, and also for hay. One man, and a horse driven by means of a line or rein, are capable of clearing from twenty to thirty acres in a moderate day's work. The grain being deposited in regular rows or lines across the field, by simply lifting up the tool and dropping it from the teeth, without the horse being stopped.

3725. The *horse stubble-rake* is a large heavy kind of horse rake, having strong iron teeth, fourteen or fifteen inches in length, placed at five or six inches from each other, and a beam four inches square, and eight or ten feet in length. In drawing it two horses are sometimes made use of, by which it is capable of clearing a considerable quantity of stubble in a short time. In general, however, it is much better economy to cut the stubble as a part of the straw.

3726. The *couch-grass rake* differs little from the last, and is employed in following very foul lands, to collect the couch-grass or other root weeds. It may be observed, however, that where a good system of cultivation is followed, no root weeds will ever obtain such an ascendancy in the soil as to render an implement of this kind requisite.

3727. *Weir's improved hay or corn rake* (fig. 371.) is adjusted by wheels, and is readily

put in and out of gear by means of the handles (*a a*) and bent iron stays (*b b*). It is drawn by one horse in shafts (*c*), and is a very effective implement.

3728. The *hay-tiding machine* (fig. 372.), invented about 1800, by Salmon of Woburn, has been found a very useful implement, especially in making natural or meadow hay, which requires to be much more frequently turned, and more thinly spread out, than hay from clover and rye grass. It consists of an axle and pair of wheels, the axle forming the shaft of an open cylindrical frame, formed by arms proceeding from it, from the extremities of which bars are stretched, set with iron prongs, pointing outwards, and about six inches long, and curved. There is a crank by which this cylinder of prongs is raised from the ground, when the machine is going to, and returning from, the field;

or when it is not wanted to operate. It is drawn by one horse, and, on the whole, answers as a tedding machine perfectly. In the neighbourhood of London, where

372

meadow hay is so extensively made, it is found to produce a great saving of labour, and is now coming into very general use.

2729. *The hay sloop or sweep* (Fig. 373.) is an implement for drawing or sweeping accumulations of hay to the cart or rick, or to any larger accumulations. Sometimes a rope is merely put round the heap, especially if it has been a few days in the cock or piled up, but the most general hay sloop consists of two curved pieces of wood, six or eight feet long joined by upright pieces, so as to form something like the back of a chair. To the four corners of this, ropes are attached, which meet in the hook of a one horse whiffle-tree (c).

2730. *Snowden's leaf-collecting machine* is for the purpose of collecting dead leaves from lawns, parks, and pleasure-grounds, and has been employed in the King's grounds at Hampton Court. The apparatus consists of a large cylindrical tub, about five feet in diameter and seven feet long which swings upon an axle, and is open at top, in order to receive the leaves as they are collected. The collectors are hollow iron scoops, or scrapers, attached to bars, extending across the machine from two iron hoops, which work round the cylindrical receiver, and, as they revolve, scrape the ground collect the leaves together, lift them up, and turn them over into the tub. The collectors or scoops

374

(Fig. 374.) are made of many distinct pieces, set in rows, with springs behind each by which any part of the scraper is enabled to give way should it come in contact with a stone, in a manner similar to the rake bars of a haymaking machine. The hoops carrying the scrapers are lowered and adjusted to meet the ground, by having their pivots supported in a lever attached to the carriage upon which it is adjusted by means of a circular rack and pinion. The scrapers are carried round as the carriage moves forward, by means of a spur-wheel, upon the nave of one of the carriage wheels, which works into a cog wheel upon the axis of the scraper frame. This apparatus is designed, beside cleaning parks and lawns of dead leaves, to remove snow from the walks, to scrape and clean roads, and for several other useful purposes. (*Newton's Journal*, vol. i. p. 205.)

#### SUMMARY. 2. Reaping Machines.

\*2731. Though reaping machines, as we have seen (153.), are as old as the time of the Romans, one of an effective description is yet a desideratum in agriculture unless the recent invention of the Rev Patrick Bell can be considered as supplying that desideratum. The high price of manual labour during harvest, and the universal desire in civilised society of abridging every description of labour will doubtless call forth such a reaping machine as may be employed in all ordinary situations and this is, perhaps, all that can be desired or expected. Corn laid down, or twisted and matted by wind and rain, or growing among trees, or on very irregular surfaces, or steep sides of hills, will probably ever require to be reaped by hand. But independently of the high price of labour, despatch, as an able author observes (*Supp. Encyc. Brit.* i. 118.), is a matter of great importance in such a climate as that of Britain. In reaping corn at the precise period of its maturity the advantages of despatch are incalculable, especially in those districts where the difficulty of procuring hands, even at enormous wages, aggravates the danger from the instability of the season. It cannot, therefore, fail to be interesting, and we hope it may be also useful, to record some of the more remarkable attempts that have been made towards an invention so eminently calculated to forward this most important operation.

**1798.** The first attempt at a reaping machine, so far as we have learned, was made by Repon, who obtained a patent for a mowing machine early in the present century. This machine was placed in a two-wheeled carriage, somewhat resembling a common cart, but the wheels were fixed upon the axle, so that it revolved along with them. A cog-wheel, within the carriage, turned a smaller one at the upper end of an inclined axle, and at the lower end of this was a larger wheel which gave a rapid motion to a piston fixed upon a vertical axle in the forepart of the carriage, and rather on one side, so that it went before one of the wheels of the carriage. The vertical spindle descended to within a few inches of the surface of the ground, and had there a number of scythes fixed upon it horizontally. This machine when wheeled along, would, by the eight revolutions of its scythes, cut down a portion of the corn growing upon the ground over which it passed, but having no provision for gathering up the corn in parcels and laying it in proper heaps, it was wholly unsuited to the purpose.

**1798.** An improvement on the attempt was made by Planchet, an agricultural implement-maker of London, some years afterwards. The principal alteration he made was in substituting for the scythes a circular steel plate, made very sharp at the edge, and hinged at the upper side like a nutcracker. This plate acted in the same manner as a very fine toothed saw, and was found to cut the corn much better than the scythes of the original machine.

**1798.** A machine, invented by Gladstone of Glastonbury, in the stewardry of Kilmadright, operated upon nearly the same principles with Planchet's; but Gladstone made his work much better by introducing a circular table, with strong wooden teeth notched below all around, which was fixed immediately over the cutter and parallel to it. The use of these teeth was to collect the corn, and retain it till it was operated on by the circular cutter. The corn, when cut, was received upon this table, and, when a sufficient quantity was collected, taken away by a rake or sweeper and laid upon the ground beneath the machine, in regular parcels. To this machine was added a small circular wheel of wood, covered with stony which, being always kept in contact with the great cutter at the back part, or opposite side to that where the cutting was performed, kept it constantly ground to a sharp edge.

**1795.** Schom of Woburn made the next attempt, and his invention, it is said, promised better than those we have mentioned. It was constructed upon a totally different principle, as it cut the corn by means of shears, and it was provided with a very complete apparatus for laying it down in parcels as it was cut.

**1796.** The next machine (Fig. 374), and one of great ingenuity and promise, is that constructed by

315

Smith, of the Domesday Cotton Works, Farnthorpe. Smith's perseverance, his successive improvements, and ingenious yet simple contrivances for remedying defects, afforded strong grounds to hope that he would ultimately succeed in rendering his machine a most valuable acquisition to agriculturists, and various circumstances have prevented Mr. Smith from perfecting his invention. He made the first trial of his machine upon a small scale, during the harvest of 1811. It was then wrought by two men. In 1812 he constructed one upon a larger scale, to be wrought by a horse; but, though he cut down several acres of oats and barley with considerable ease, it was found that when met by an acclivity the horse could not move the machine with proper effect. In 1813 he made a more successful attempt, with an improved machine, worked by one man and two horses, and (1816) it was still further improved by an additional apparatus, tending to regulate the application of the cutter when working on an uneven surface. This ingenious machine has been again tried, in September 1816, and with much success. A Scotch acre (1½ acre English) of beam was cut down with ease in an hour and a quarter. The trials made with it on wheat, though not extensive, were satisfactory; and in reaping oats, the corn was laid down in the most regular manner. The cutter of this machine is circular and operates horizontally. It is suspended to a drum connected with the forepart of the machine, its blade projecting some inches beyond the periphery of the drum; and the machine is so constructed as to communicate, in moving forward, a rapid rotatory motion to this drum and cutter by which the stalks are cut, and falling upon the drums, are carried round and thrown off in regular rows. This most ingenious piece of machinery will cut about an English acre per hour during which time the cutter requires to be four times sharpened with a common scythe alone. The expense of this machine is estimated at from thirty to thirty-five pounds. If properly managed it may last for many years, only requiring a new cutter every two or three years, a repair which cannot cost much. This promising invention, which attracted a good deal of notice a few years ago, remains, it is believed, as it was then, in a state not calculated for extensive use. Mr. Smith's large expense in the cotton manufacture may have prevented him from continuing his experiments; and it is understood that the time he has already devoted to it has been without sufficient remuneration or encouragement.

**1797.** Another reaping machine (Fig. 375 and 377) is the most recent as well as the most perfect invention of this description. The frame-work of this machine (A) may be made lighter or stronger according to circumstances; A and C are four wheels upon which it is mounted, of whatever form it is made; A have their axles at right angles to their horses, and are 24 feet diameter. For steadiness sake the axles are made of cast-iron; the wheels are from five to six inches broad at the rim, and are surrounded with a slight hoop of iron. Where they make contact in the rim, when the ground is soft they would sink in it, and draw without doing any motion to the central parts of the machinery. The small wheels (D), which support the front of the frame, are (like the large ones) made of wood; they are fourteen inches in diameter, and six inches broad at the rim, with a very slight hoop of iron round them. Their axles, which are of iron, are secured to the frame, and are about 12

The Rev. Patrick Rafter and the Rev. James O'Connell del.

the machine; and, in appearance, they push the machine before them, but, in reality, they are drawing the same as in the plough. *d* is a small rod of wood, or holt, which the driver holds in his right hand, by the passing of which to him, or putting it from him, he controls the machine straight forward. The dotted lines in this plate are a continuation of the plate with the *spring* and *hook* attached. The machine is turned, at the end of the ridge, by the following contrivance:—The two wheels *ee*, in the body of the machine, are joined to the lever *f* by an upright movable axle. These wheels are similar to the two (see) on the front of the frame: they have a strong iron axle, which is made as long as to let the wheels continuously turn between the crank-rod (*cc*) and the frame of the machine. In order that this piece of the apparatus may be used with advantage, the beveled wheel *i* is not placed upon the middle of the main axle (*cc*), but just one foot from the end of it, as is seen in the engraving. This throws the crank-rod (*cc*) nearer the side of the machine, thus leaving plenty of space for the turning apparatus. In the middle of the horizontal axle of the wheels *ee* there is an upright standard of iron sufficiently strong, and firmly joined to the horizontal axle. This upright standard of axle passes through the middle of the lever *f* (which is of wood, and, at this part, about five inches square, about twenty inches from the end of it. Upon the top of the upright standard there is placed a segment of a wheel (*g*), with the teeth on the lower side, which is worked by a small pinion of six teeth upon the end of the rod *g*. This pinion is not seen in the engraving, as it is completely concealed by the segment *g*. The rod *g*, and the small pinion upon it, are turned round by the handle *h*, the pinion moves the segment *g*, which, being firmly fixed to the upright standard, turns the small wheels *ee* either way. When the machine is cutting, the wheels *ee* are just parallel to the surface, and in this position they assist the machine in passing a furrow without allowing the surface to come in contact with the opposite side of it. But when the machine is to be turned round, they are turned, with an angle to the path of the machine, by the handle *h*, and the rod *g* being fixed in that position by a screw near the handle, the lever *f* is then pressed down, and fixed with a screw to the frame of the machine. In pressing down the lever *f*, the small wheels *ee* which before were about two inches from the ground, are pressed to the earth: about two or three inches below the natural level of the machine. Of course the two front wheels (*cc*) are lifted two or three inches from the ground, and the surface considerably more, thus insuring them from accident while turning round. The machine now rests upon the two large wheels *aa*, and the two small ones *ee* of the lever and the two front wheels (*cc*) go for nothing, as they do not touch the ground. But the axle of the small wheels *ee* being placed with an angle to the main axle (*cc*) of the large wheels *aa*, the machine will naturally turn round upon the horses being moved slowly forward, the greater the angle formed by the two axles, the less space will the machine require to turn upon. In turning the machine, however, attention must always be given to disengage the large wheels *aa* from the main axle (*cc*): this is done by shifting the coupling boxes *aa* by means of the handles *aa*. The apparatus *ll*, or collector, is placed exactly above the bottom *ll* in 2½ feet in diameter made of wood, as slight as may be. The supports *kk*, in the interior machine, were made of iron, but now the two side-bushes of the machine are made of a piece of wood, with a central cut upon it, similar to the base of a plough, but raised with a roughened angle, as near the form of the iron supports in the plate as possible, and continued horizontally till their points are exactly above the movable bar *ooo*. The points *pp* are made of iron, bent as in the plate, to allow the collector (*ll*) to turn round. At *ggg* are strong iron screws, working in slots placed in the wooden part of the supports, which serve the double purpose of uniting the iron part to the wood, and allowing it to be drawn forward, or pushed backward, as occasion may be, by either shifting to another hole, or which is better, by long slots in the middle of the bar. Long iron rods, the collector to be placed forward, and short iron rods to be taken back. At *ss* are two perpendicular rods, which slip in holes in the points of the supports; by the moving of which, upwards or downwards, the collector (*ll*), which turns in sockets in the lower ends of these rods, is lowered, or heightened, according to the length of the corn to be cut. The rods are fixed in their places by screws in the end of the supports. The collector is turned by a cross bar, or shaft, passing over the two pulleys *mm*. A piece of slight canvas is put round the rollers *nn*, fixed to the shaft *ss*, as before described. The lower ends of the rollers have a shield of plate iron round their guides, to prevent the cut corn from varying, which it does effectually. The bushes of the roller *nn* are made of cast iron, to tighten the chains *ss* a little, to prevent them from slipping the pulleys, as they lengthen a little by using, especially when new. Fig. 376 is a representation of the machine in full operation. About six or eight yards of the field require to be cut at the ends to show the machine to turn without interfering the corn, which may be done by the machine itself: the corn is standing nearly upright, a convenient number of ridges may be taken in and out by going round them; but if the corn is standing, and the field free from deep furrows, it may be cut by going round and round till it is stretched in the middle. One man, as seen in the plate, is sufficient to manage the whole operation. The cutting, collecting, and laying are the three principal parts of this machine, which have been all, more or less, explained in the general description given above. But as they are particular, a few words on each of these heads may still be necessary, that the machine may be completely understood in all its bearings. First, then, with regard to the cutting: it is desirable that the machine should do her work, and nothing more. If the motion of the cutters were too slow, she would not clear the ground; and if it were too quick, there would be a useless expenditure of power and machinery. Let it be remembered that the large outer wheels *aa* are 3½ feet in diameter, that the beveled wheel *i* has sixty teeth, and that the crank-rod pinion has ten; and that the cutters have twelve inches of a cutting edge. The diameter of the wheels *aa* being 3½ feet or forty-two inches, their circumferences are 131·9477 inches; every revolution of them will pass over nearly 132 inches of the ground's surface; but there being ten teeth in the crank-rod pinion, and sixty in the beveled wheel, every revolution of the wheels *aa* will turn the crank-pinion six times, and, of course, the crank six times. But every turn of the crank-pinion gives two cuts, and each stroke of the cutters clears twelve inches of the ground, because they have twelve inches of a cutting edge; therefore, one revolution of the wheels *aa* gives twelve strokes of the cutters, and clears twelve times twelve, or 144 inches of the surface of the ground. But one revolution of *aa* passes only over 132 inches of surface; therefore, the cutters are calculated to cut, in one revolution of *aa*, twelve inches more than enough, that is, one inch each stroke. This, however, is perhaps nothing more than is advisable to calculate upon, making allowance for the operation of the machinery, the partial dragging of the wheels, &c. &c. Secondly, the collector (*ll*) must not move too slowly, but it should retard the corn from falling upon the canvas, and it must not move too quickly, but it should strike ripe grain. As before stated, it is 2½ feet in diameter, that is, 31·4159 inches in circumference. But one revolution of it is a pass over 31 inches of surface; therefore, that the collector (*ll*) may just touch the corn, without bringing it back, or retarding it from naturally falling back, it must make 1½ revolution for every one that *aa* makes. Since there are six arms in *ll*, every arm will touch the standing corn at equal distances of 157 inches. The pulley *mm* makes six revolutions for one that *aa* makes; it is six inches in diameter, and the pulley *nn*, upon the axle of *ll*, is nine inches; therefore it revolves 1½ times for one that *aa* turns round, and the collector (*ll*) revolves four times for one that the large wheels *aa* revolve. But  $6 \times 31 \cdot 4159 = 376 \cdot 98$  inches, the space passed through by the circumference of the collector, while the machine moves forward only 132; the difference of which is 244·98, the space that the collector passes over more than the machine, during one revolution of *aa*. Therefore, every inch of the corn is brought back 1½ inch nearly, by the collector, which is sufficient to insure the better backwardness of the cutters; and yet it touches the corn so gently, that it is impossible that it can injure it in the slightest degree. A quicker and slower motion, however, is advisable, when the corn is green, by having one or three screws upon the pulleys *mm* and *nn*; and then, by shifting the bolt, a different motion is produced. With regard to the canvas, it is necessary that it should revolve as much as the ground passed over by the machine; that is, while the wheels *aa* make one revolution, or pass over 132 inches of the surface 132 inches of loose of canvas should pass over the rollers. As before stated, the collector has thirty-six teeth, and is thirteen, so that the roller *nn* will give two revolutions for

one of  $w$ . But  $w$  revolves six times for one revolution of the wheels  $a$  &  $b$  hence the roller  $v$  will revolve twelve times for every revolution of  $s$ . The diameter of the rollers is four inches; their circumference, therefore, are nearly 12.56 inches, twelve revolutions of which will give 150.72 inches. As before stated, one revolution of  $s$  gives only 12.56 inches, wherefore there is a preponderance of motion, on the side of the canvas, of 138.16 inches for every revolution of  $s$ . This velocity is necessary to insure the canvas of clearing itself in all cases; and, with a smart velocity the cut corn is laid down with a greater angle to the path of the machine. It may here be observed, that it is often found convenient to have the canvas so lay down the corn on either side of the machine, according to the direction from which the wind is blowing. This may be done with a double wheel at  $x$ , with a handle in the usual method employed for reversing the motion of the rollers of the threshing machine. It were desirable, too, if possible, to have the canvas bordered with a drying oil or gum, or some other substance which would prevent it from contracting with moisture; as the slightest shower or dew of a morning, contracts it so much, as to render the implement useless until the corn is perfectly dry.

2738. *An estimate of the probable value of Bell's reaping machine* may be formed from the reports signed by numerous practical farmers, who were spectators to different trials made in 1829 and 1830. In September, 1829, the machine was tried at Fowrie, in the county of Forfar before forty and fifty landed proprietors and practical agriculturists, who signed a declaration, stating "that the machine cut down a breadth of five feet at once, was moved by a single horse and attended by from six to eight persons to be up the corn and that the field was reaped by this force at the rate of an imperial acre per hour" (*Gard. Mag.* vol. v. p. 600.) In September 1830, the machine was tried at Moncrie in Forfarshire in the presence of a still greater number of persons, who attest that it cut, in half an hour nearly half an English acre of a very heavy crop of oats, which were lodged, thrown about by the wind, and exceedingly difficult to harvest. It was tried in a number of other places in Forfarshire, Perthshire, and Fifeshire, and the general conviction appears to be, that it will soon come into as general use among farmers as the threshing machine. (*Gard. Mag.* vol. vi.) The price is, at present, between 300 and 350, but if it were once in general use, probably the cost might be lowered; but even that price would be saved out of the usual sum paid for manual labour during only one harvest by an extensive farmer. Few men deserve better of his country, and indeed, of every civilized country where agriculture is practised than Mr. Bell, for surely that inventor must ultimately be of great benefit to men and women which enables them to do by horses, oxen or steam, that which they have hitherto done by a most severe description of manual labour rendered doubly oppressive by the season of the year in which it must necessarily be performed.

2739. *A machine for reaping and at the same time sheaving corn*, was invented in the year 1828, by Mr. Henry Opta, school-master at Bennington, near Alnwick, Northumberland. In 1823, Messrs. Brown, iron founders in Alnwick, advertised that they would furnish machines of this sort complete for sheaving corn at the beginning of harvest. No farmer however could be found who would go to the expense. The operation of the machine was satisfactory and it was estimated to cut fourteen acres per day. An engraving and description of it will be found in the *Mechanic's Magazine*, vol. v. p. 60. In the same work (vol. i. p. 145) will be found an engraving of a mowing machine invented by Jeremiah Hally of Chester County United States, about 1821 and said to answer well, and to have been extensively used. Whoever contemplates further improvements in this description of machinery would do well to begin by making himself master of all the foregoing inventions.

2740. *Gladstone's machine for reaping beans* (fig. 378) has been used in several parts

of Scotland with complete success. The framework of this machine is the same as that of a common plough. To this is added the knife ( $a$ ), which is a plate of steel, screwed to a piece of wood, to keep it from bending up and down; this wood being screwed to the framework. There is a wheel ( $b$ ) to keep the knife when in motion in a horizontal position. The cutting edge of the knife ( $c$ ) has teeth, or serratures, on the upper side ( $d$ ) the under side ( $e$ ) is flat.

One horse and a man will cut with this machine from four to five acres a day, with ease, and perform the work as perfectly as by manual labour.

2741. *A machine for reaping the heads or seed-pods of clover* (fig. 379), where the

second growth of that crop is left to stand for seed, has been used in some parts of Norfolk and Suffolk. It consists of a comb, the teeth of which are lance-shaped, very sharp, and set close. This comb is affixed horizontally to the fore part of the bottom of an open box or barrow which is drawn by one horse and guided by a man, who empties the barrow in regular lines across

the field by means of an implement ( $a$ ), which serves also to clean the teeth.

2742. *A machine for mowing clover* has frequently been attempted, but not yet perfected. One by Plucknot, of the Blackfriars Road, London, succeeded tolerably, but never came into use: it consisted of circular knives put into rapid motion, and the cut stalks guided to one side by a revolving cradle, like that attached to corn scythes, (2400.) It never came into use.

SECT. VII. *Mechanics of Deportation.*

3743. *The carriage or conveyance mechanics of agriculture are chiefly carts and waggons, and their several varieties.*

SUMMARY. 1. *Carts.*

3744. *Carts, like other implements, vary in their forms and modes of construction, according to the nature and situation of the roads, and many other local circumstances; but, for the purposes of farming, those of the single-horse kind are in general the most advantageous and useful. The advantages of single-horse carts, Lord R. Seymour observes (Ann. Ag. xxvii.), are universally admitted, wherever they have been attentively compared with carriages of any other description. A horse, when he acts singly, will do half as much more work as when he acts in conjunction with another, that is to say, that two horses will, separately, do as much work as three conjunctively. This arises, in the first place, from the single horse being so near the load he draws and, in the next place, from the point or line of draught being so much below his breast, it being usual to make the wheels of single-horse carts low. A horse harnessed singly has nothing but his load to contend with, whereas, when he draws in conjunction with another, he is generally embarrassed by some difference of rate, the horse behind or before him moving quicker or slower than himself. He is likewise frequently inconvenienced by the greater or less height of his neighbour. These considerations give a decided advantage to the single-horse cart. The very great ease with which a low cart is filled may be added; as a man may load it, with the help of a long-handled shovel or fork, by means of his hands only; whereas, in order to fill a higher cart, not only the man's back, but his arms and whole person must be exerted. To the use of single horses in draught there can be no objection, unless it be the supposed necessity of additional drivers created by it: the fact however is, that it has no such effect for horses once in the habit of going singly, will follow each other as uniformly and as steadily as they do when harnessed together, and accordingly we see, on the most frequented roads in Ireland, men conducting three, four, or five, single-horse carts each, without any inconvenience to the passengers such, likewise, is the case where lime and coal are generally carried upon pack-horses. In some of the northern counties of Britain also, one man manages two or three, and sometimes more, one-horse carts.*

3745. *Carts drawn by one horse, or by two horses, says a writer whose authority is unquestionable (Supp. Encyc. Brit.), are the only farm carriages of some of the best cultivated counties, and no other are ever used in Scotland. Their load depends upon the strength of the horses, and nature of the roads; but, in every case, it is asserted that a given number of horses will draw a great deal more, according to some one third more, in single-horse carts than in waggons. Two-horse carts are still the most common among farmers in Scotland; but those drawn by one horse, two of which are always driven by one man, are unquestionably preferable for most purposes. The carriers of the west of Scotland usually load from a ton to a ton and a half, on a single-horse cart, and no where does it carry less than 12 cwt. if the roads are tolerable.*

3746. *Wheels, such as are broad, with concave or convex rims, are common in England, in Scotland the wheels are generally narrow, though broader ones are beginning to be introduced. Those used for the common, or two-horse, carts, are usually about 4½ feet high, and mounted on iron axles. The advantages of broad cylindrical wheels have been illustrated with much force and ingenuity in several late publications. (Communications to the Board of Agriculture, vol. ii. and vol. vii. part i.)*

3747. *Large wheels to carts, drays, &c. will, besides greatly increasing the facility of draught, tend to lessen the number of accidents to which all two-wheeled carriages are liable, from the shaft-horse falling down. To render this more evident, let us first examine fig. 380., which is a rude sketch of a cart constructed in the usual manner,*

and supposed to be loaded with bricks, stone, sand, or other heavy material. While thus loaded, and the horse is in an erect position, the centre of gravity (*g*) is almost directly over the axle-tree, in which state the body of the cart is nearly balanced, or only pressed upon the back of the horse with a force equal to a few pounds weight. But the horse is supposed to have fallen: the consequence is, that the centre of gravity is thrown much more forward; the body of the cart and its load becomes divided by the line *a b*, perpendicular to the axle-tree, into two very unequal parts, *c* and *d*; the whole of the increased portion (*c*) in front of the line acting as a weight upon the horse, and only partly counterbalanced by the diminished portion (*d*) behind the line. It frequently happens that this increased weight, so suddenly thrown upon the shafts, snaps them short off, and at all times, tends to prevent the horse from rising until part of the load is removed. By adopting the larger wheels, and the bent

axis (*fig. 381*) the cart, &c. becomes much less liable to such accidents, because the

centre of gravity (*g*) and the centre of suspension (the axle) are brought much nearer together the former being placed nearly over the latter, at a small distance only from it. A horse falling with a loaded cart so constructed, will experience but little increase of weight upon him while down: the cart will be divided as before, by the line *ab*, into two parts; but it will be observed, these portions differ but little in their respective magnitudes. The centre of gravity (*g*) will be thrown forward, but in a very trifling degree. In carts, &c. it will almost always happen that the centre of gravity will be above the point of suspension (the axle) but in gigs, &c. the body may be placed so low that the centre of gravity may fall below that point, when the body will always maintain an erect (i. e. a horizontal) position, and, should the horse fall down, will operate to lift him up again. A gig so constructed would be almost beyond the possibility of those serious, and frequently fatal, accidents, which occur from the falling of the horse. (*W. Biddoley, jun. in Mech. Mag. vol. xii. p. 304.*)

3748. The power of wheels has no dependence on the height of the wheels, or the length of their spokes, but depends wholly on the power of draught that is joined to their axis, and to the forward motion, or the progress of the carriage. If the carriage were placed upon skates completely polished, and upon smooth ice, it would be drawn by as little power as if it were placed upon wheels. The use of wheels is to lessen the resistance to the carriage by friction, or rubbing upon the ground, or upon the floor upon which the carriage is to be moved: that resistance is least of all when the ground is hard and smooth, such as a rail-road of iron. It increases upon soft and upon rough ground: and it increases still more when the carriage must be drawn up an ascent, according to the steepness of the ascent, because the power of draught must be able to lift the carriage, it may be said, step by step, up the ascent; and when the ascent is soft or rough, more power of draught is necessary. When the wheels are dashed they plough the soft ground and grind the rough ground, and thereby they increase the power of resistance, and require more power of draught to overcome the absurdity of their own form; and thus they cause the continual shaking of the joints of the carriage, and the wearing of the iron end of the wood of which it has been made. Narrow wheels are drawn rather more easily through small loose stones: but, upon every other kind of ground, broad wheels that are rollers are drawn more easily, or with less power, and the benefit of them to the roads is greater according to their greater breadth. High broad wheels do not sink so deep into soft ground as low wheels do; but, if the low wheels be made broader, the benefit obtained will be in proportion to the additional breadth. The axes of high wheels turn seldom round, or the wheels turn seldom round the axes, which is an advantage: but high wheels must be weightier than low wheels, which is a disadvantage. High wheels are useful to carry great stones, or great trees, under the axes; and loads of every kind alive as well as dead, ought to be hung as low as possible. And every load ought to be hung, or placed, upon springs, which will allow the carriage to be lighter; and the lower it is hung or placed, it will be so much safer from overturns, there will be less shaking, and less power of draught will be required. (*Sir Alex. Gordon, in For. Mag. vol. xx. p. 180.*)

3749. The construction of wheels has been much improved by the introduction of cast-iron nave or stocks. These stocks are found particularly suitable for warm climates, and scarcely any others are exported. Messrs. Morton of Leith Walk, have renewed the spokes in them after they have been in use twenty years, and found the stocks as good as when new. (*Gard. Mag. vol. vi.*) In England wrought-iron spokes have been employed, which are found to succeed perfectly, and, from their durability will, in the end, be found cheaper than wood.

3750. Jones's improved iron wheels (*fig. 382*) are formed wholly of cast and wrought iron. The felly or periphery of the wheel (*a*), is made of cast iron, with conical holes on the outside, contracting towards the centre, through which the spokes, made of iron rods, are to be passed, and secured in the box, or nave (*b*), near the centre of the wheel, by nuts screwed on to the reverse end of the rods, by which means they are drawn tight. (*Newton's Journal, vol. i. 3d Series, p. 154.*)

3751. A great improvement in the construction of axes for carriages, carts, and waggons, has been made by George Burges, Esq. M. A. of Cambridge. Instead of one circle moving within another, as in all common axes, or one circle moving within another this other having grooves for retaining oil in the manner of the patent axes. Mr Burges's axle is a circle (*fig. 383*).

*a*) moving within six points, formed by six equal convex segments, which hold oil in their angles (*b*); the friction is thus reduced to a minimum in theory; and with case-hardened iron, and abundance of oil, we should think it could not be otherwise in practice. Mr Burges has had the axes of his own carriage constructed in this way for some years. (*Gard. Mag. vol. v.*)

3752. The Scotch one-horse coup cart is used either without or with (*fig. 384*) a frame for the purpose of

building on a greater load of hay, straw, or corn in the shaft. This frame is held on by no fastening, but remains in its place from being fitted to the exact width of the body of

384

the cart. On drawing out an iron pin, the fore part of the body rises up from the shafts, while the other end sinks, and allows the load, whether of dung, earth, or stones in the close cart, or of hay, or sheaves of corn, on the cart and frame, to fall to the ground.

2753. The Scotch corn cart (*fig. 385.*) consists of open framework, with a boarded bottom, and is used solely for the purpose of carting hay, corn in the sheaf, or similar materials. It is light, cheap in construction, and contains a bulky load, which, being lower and more extended than a load on a coup cart with a frame, is less likely to be overturned.

385

2754. The Scotch two-horse cart differs little from the one-horse cart, except in being larger. To

prove the inferiority of double to single horse carts, Gray observes, "that whatever greater part of the load is placed before the centre of gravity, which is always in the axle, must rest constantly on the horse that is in the shaft. In going down hill this burden must be considerably increased, especially if the load be high above the centre of the axle, or the descent steep, and the additional burden upon the shaft-horse is always in proportion to these two causes united. But there is another disadvantage, for, unless the line of the draught of the foremost horse be exactly in the line from the hook of his collar to the centre of the axle (which is hardly possible), he will perpetually be pulling down the hindmost horse, or, in other words, will be giving him more weight to carry. For, as the traces of the foremost horse are generally fixed upon the shafts, this throws his line of draught at a considerable angle above the centre of the axle; from which it is evident, that although the road be ever so level, yet in every double or two-horse cart, the foremost horse must either not draw at all, or must bring additional weight upon the horse in the shaft, which weight will always be in proportion to the force with which the trace-horse draws, and the largeness of the angle which the line of his draught makes with the line from the hook of his collar to the centre of the axle. Besides, unless the driver be more careful than ordinary, and keep the trace-horse to his duty, the other one has not only this great weight to carry, but also the whole load to draw. The angle is increased considerably when the trace-horse is of a lower size than the one in the shaft, which may frequently happen; and, by this means, a still greater burden is laid upon the back of the horse employed in the shaft."

386

2755. Improved two-horse carts. (*fig. 386.*) It may be suggested to those who are fond of employing two-horse carts, that, in order to adjust the traces of the fore-horse

with as little injury as possible to the one behind, and by this means make both their powers coincide, two iron frames are fixed into the axle, in each of which is placed a sheave or wheel. Upon these sheaves pass a rope or chain (a). In the outside of each shaft is fixed a long iron staple; and on each staple is placed an iron slider (b), having liberty to shift either forward or backward the chain from the collar of the shaft-horse is hooked into the eye of the slider; and the chain or rope, by which the foremost horse draws, passing from his collar (c), round on the sheave at the axle, is hooked into the other eye of the slider. By this means the two horses are so connected, that, if the one shall relax, immediately the exertion of the other horse presses the collar hard upon his shoulders, so that he must either exert himself or be pulled backwards. Thus the exertions of the two horses are united, so as to form one power applied to the cart, in place of two powers working generally against one another, which must be the case in the common way of attaching two horses to a cart. But, by this way of yoking, the shaft-horse receives no additional burden from the exertion of the trace-horse, as they both draw from one point, which is the centre of the axle, to the hooks of their respective collars, by which their powers must nearly coincide. If this coincidence does not take place, it is evident that the two horses will, to a certain degree, be pulling against one another, which must be extremely distressing to each in his turn, especially to the one in the shafts. The same principle, as will afterwards appear, has been employed in yoking horses to threshing machines.

\*2756 The corn cart has a longer body than the close cart, and the sides and ends are open, and support two rails along each. It is made to fit the axle and wheels of the close cart, and is chiefly used in haytime and harvest, when it is supposed to admit of laying on a larger load of sheaves or hay than the cart and frame.

2757 Lord Somerville's drag-cart (fig 387) is constructed with a contrivance for

checking or regulating the rapidity of its motion in going down hills or other declivities. The method for adjusting the position of the centre of gravity of the load, and to prevent its pressing too much on the axle in going down hill, is by a toothed rack, screwed to the front of the cart, and worked by a pinion and handle (a) immediately connected with the pole. By means of this pinion and rack the front of the carriage is elevated more or less, in proportion to the declivity of the hill, by which means the weight of the load is made to bear more on the axle and less on the necks of the oxen. A friction drag (b) is made to press more or less on the side of the wheel, according to the steepness of the descent: the one end of it is connected with the tail of the cart by a small chain, and the other end to the front, by means of a toothed rack, which catches on a staple in the front of the cart, by which the pressure of the friction-bar may be regulated at the discretion of the driver: the notches or teeth in this rack, it is observed, should be as close to each other as circumstances will permit.

2758 The advantages of the friction-drag and other contrivances, are said to be, 1st, The method, which is equally simple and expeditious, of adjusting the centre of gravity of the load, so as to have a proper bearing on the horses or axle, in going down hill. 2dly, The method of applying friction to the side of the wheel, to regulate the motion of the carriage in going down hill (instead of locking the wheels) the advantages of which method appear to be as follow: namely first, the pressure and degree of friction may with great expedition, be adjusted to the steepness of the declivity so that the carriage will neither press forward, nor require much exertion to make it follow the cattle. secondly the friction is so applied to the wheel, that a given pressure will have twice the effect in retarding the progress that it would have if immediately applied to the body of the carriage, or to the axle. and, by applying the friction on both sides of the wheel, the risk of heating and destroying the friction-bar is much less than if the same degree of friction were applied in one place. 3dly, This apparatus is so conveniently placed, that it can be instantly applied or adjusted, without stopping the carriage, or exposing the driver to the same danger as in locking a wheel. And, 4thly, This contrivance will assume yet a greater importance when applied to both the hind wheels of waggon, by which means the resistance may always be proportioned to the steepness of the descent, the tendency up of the road prevented, the unnecessary exertion of the cattle in drawing the loaded carriage down hill avoided, the danger to which the driver is sometimes exposed in locking the wagon-wheels totally avoided, and the time now lost in locking and unlocking the wheel saved in the proportion.

2756. *Reaper's stop drag for carriages going down hill* (Figs. 388, 389, and 390.)

consist of five or more pieces of wood, "united on the outside by a strong jointed iron hoop the wood pressing upon the nave of the wheel. The first, a fixed pivot (a), from the hoop, is fixed to the under side of the frame of the cart from the other extremity of the hoop of the brake proceeds a bar (b), which slides through the plate or socket (c) fixed

to the side of the cart frame; a vertical perforation is made through the bar (b), just behind the plate, to receive the pin (d), which is likewise chained to the shaft. This pin, so placed, prevents any force applied to the chain from tightening the brake on the nave of the wheel. Fig. 389 represents the interior of a wheel on level ground, the nave surrounded by the brake, which, by its own gravity is hanging loose, leaving the wheel perfectly free. Fig. 390 shows a wheel on a declivity the chain drawn tight by the pressure of the breeching on the horse the brake, of course, closely surrounding the nave, and forming an effectual drag. Fig. 391 is a bird's-eye view of the whole apparatus, exhibiting the framing of the cart, the shafts, wheels, and brakes; the chains also are shown, passing from the bars on each side, each round a horizontal pulley on the shaft, and attached to the ends of the breeching. Thus it is evident that, when a cart, furnished with this drag is going down hill, the load, pressing the breeching against the horses, draws the brake tight by means of the chain and produces a

friction on the nave proportioned, in some measure, to the declivity. When backing upon level ground, by inserting the pin (Fig. 388 d) through the bars of the brakes, the wheels will be kept free. This drag is to be applied to the naves of the carriage wheels, with a chain attached, fastened to the breeching of the horse, and a small pin on each side of the shaft is to go into the hole of the bar of the drag. If one of the pins be taken out, one wheel will be dragged and the other not. By leaving out both pins, the two wheels are dragged in going down hill, by the breeching bearing against the horse. The wheels will revolve round on a level road, and in going up hill undrag themselves. When the wheels are braced, two or three tons weight have very little pressure on the horse in going down hill. If two loaded carts should meet on a narrow hill by unhooking the drag-chain from the breeching and hooking it to the tub-chain (back chain), the horse can be put back with the greatest ease and safety. When the horse is put back against the hill, the two pins must be put in the bars of the drags. The drag consists of a wooden brake, applied round the nave of each wheel, in pieces which are encircled and connected by a jointed iron plate. The small bar attached to one end of this brake slides freely through a corresponding hole in a plate fixed at right angles to the shaft. A hole is drilled through this sliding bar, for the purpose of admitting a pin or forelock, chained to the shaft. To each end of the breeching is attached a chain, which, passing through a horizontal sheave, or pulley, on the upper surface of each shaft, is ultimately fixed to the bar of the drag. While the bolts or forelocks remain in the holes behind the perforated plate before mentioned, it is evident the brake cannot tighten upon or drag the wheel but, on either of those pins being removed, the wheels become immovable." (*Smith's Mechanic*, vol. ii p. 332.)

2757. *Kneebone's drag for two-wheeled carriages* (Fig. 392.) is composed of a piece of wrought iron, curved to the exact form of the circumference of the wheel, with a chain, to be fastened to the near shaft, to keep the drag properly under the wheel. When the drag is out of use it may be hung on hooks, at the under part of the tail of the cart. The weight of this drag is usually from sixty to eighty pounds. "This simple contrivance has never failed to be effectual in retarding carts, or any two-wheeled carriages, while descending hills, taking off the great burden from the shaft horse, and

permitting the carriage to descend with the greatest ease and safety in the most mountainous country. It may be applied to any kind of road, and is not subject to the inconvenience of locking poles, which, on rough roads, among loose stones or deep ruts, are very apt to overturn carts by the sudden resistance they meet with. Deep ruts, or loose stones, have not been found to lessen the advantages of this drag." (*Smith's Compend. of Practical Inventions*, p. 322.)

2761 The improved quarry cart has a bend in its iron axle, which brings it within fourteen inches of the ground, although moving on wheels more than five feet high. In the ease with which it is drawn, loaded, and unloaded, it is superior to the common cart in the proportion of seven to three.

2762 The three-wheeled cart is a low machine, on wheels about two feet in diameter, the third wheel placed in the middle before, and generally of smaller size than the two others. It is used for conveying earth or gravel to short distances, as in canal and road making; and for these purposes it is a most valuable machine, and in very general use.

#### SUMMARY 2. Waggon.

2763 Waggon constructed in different forms, and of various dimensions, are made use of in different districts of the kingdom and for the most part without much attention to the nature of the roads, or of the articles which are to be conveyed by them being, in general, heavy, clumsy, and inconvenient. Waggon require much more power in the draught than carts, and are far from being so handy and convenient, which is certainly an objection to them, though they carry a much greater load. There can be no doubt that more work may be done in any particular time with the same number of horses, by carts than by waggon, in the general run of husbandry business, especially where the distance is small between loading and unloading. Waggon may perhaps be the most proper sort of conveyances for different sorts of heavy loads to a considerable distance, but for home business, especially harvest, and other field work which requires to be speedily performed, carts seem decidedly preferable.

2764 Waggon, though they may possess some advantages over carts in long journeys, and when fully loaded, the editor of *The Farmer's Magazine* observes, are now admitted to be much less convenient for the general purposes of a farm, and particularly on occasions which require great despatch, as in harvesting the crop.

2765 On the loading of waggon much of the value depends. "A waggon or other carriage, on four wheels of equal diameter is of lighter draught than those in common use, having the fore pair of wheels of less diameter than the hind, but if the load be placed on the fore and hind wheels in the same proportion that their diameters bear to one another, nearly all the advantages of having wheels of equal diameter will be obtained. Thus proportioning of the load cannot at all times be effected in carriages of the ordinary description, even if wished, because the body of the vehicle must be equally filled with the goods to be removed, or a great loss of room would occur." (*W. Baskley, in Mech. Mag.* vol. xii. p. 173.)

2766 The distribution of the load between the wheels, so as to render the difference in their size a matter of no importance, may be effected by adopting a plan recommended by Baskley before quoted. In a sketch of a waggon, which this engineer has given in the *Mechanics Magazine* (fig. 393) the hinder wheels are unusually large, and are so situated as to carry four-fifths of the weight when the body is fully loaded, with less than a full load they may be made to carry the whole weight, by placing it over them.

To admit of such large wheels being used the axle is bent, as will be better seen by referring to fig. 394, which is a section of the hinder portion of the carriage. It will also be seen that this part of the carriage is supported by three springs, two only being used in the fore part. Simple as this arrangement may at first sight appear, it will be found to possess a great superiority over waggon of the usual construction. The ease with which great loads may be transported upon wheels of large dimensions has been a long and well established fact, but, at the same time, it is one of which the builders of carriages have never so fully availed themselves as they should have done. In passing over a rough or unevenly paved road (such as yet abound in many parts of our metropolis), a small wheel sinks into every little hollow and the axle, if notched, would be found to describe a line almost as curved and irregular as the surface of the road. A large wheel on the same road would partake but slightly of its inequalities, and the line described by the axle would be found to deviate but little from a straight line; indeed, with a wheel sufficiently large, the axle would describe a perfectly straight line. In the latter case the friction, and consequently the draught, would be little more than if the carriage ran upon a rail-road. The larger therefore we use the wheels, the nearer we approach the desirable point of effect. By the application of the bent axle (fig. 394), large wheels, so highly necessary in these cases, might be employed without raising the body of the carriage. (*W. Baskley, ibid. in Mech. Mag.* vol. xii. p. 174.)

2767 The Gloucestershire waggon, according to Marshall, is the best in England. By means of a crooked wide-rail, bending archwise over the hind wheel, the bodies or frames of them are kept low without the diameter of the wheels being much lessened. The bodies are likewise made wide in proportion to their shallowness, and the wheels run six inches wider than those of most other waggon, whereby advantages in carrying top-

kinds are evidently obtained. Rudge, in his survey of the above district, says, that in many districts, waggons are the principal carriages employed in getting in the hay, and are either full-bedded, or with three-quarter beds. The former have the advantage of a greater length of bed, but are not so convenient for turning the latter, though diminished in size, have the convenience of locking the fore wheels, and turning in almost as narrow a compass as a chaise, in consequence of the bed being hollowed out on each side near the middle, to admit the exterior part or fellows of the fore wheels. Both waggons are capable of carrying nearly the same weight; though the former, being deeper in the bed, is somewhat better adapted for the carriage of heavy articles, such as bags of corn, &c. For the purpose of harvesting, or carrying hay and straw, their length and width are increased by light ladders before and behind, and of similar contrivances called "rathes," the whole length of the sides. The ladders are put on and taken off at pleasure, in both kinds, but the side additions are generally fixed, except in the strut-headed, which are in use on the western side of the Severn, in these they are made removable, so as to leave the bed quite naked.

2768. The *Berkshire waggon* (fig 395) is constructed on a simple and convenient principle, not having the usual height or weight of other waggons, while it possesses

sufficient strength, and is easy in the draught. An improvement suggested is, that of leaving the space sufficiently deep in the body or bed for the fore wheels to lock round in the shortest curve, as, in the present manner of its construction, a great deal

of time is lost in turning at the ends of the swarths, in carrying hay, and on many other occasions. In this way the inconvenience may be removed, without doing the smallest injury to the symmetry or strength of the carriage.

2769. The *Norfolk cart and waggon* is formed by adding a pair of fore wheels and shafts to a common cart, connected by a pole from axle to axle. It is said to be light, cheap, and convenient, and capable of carrying nearly as much hay or straw as the Berkshire waggon.

2770. *Road's patent waggon* (fig 396) is a contrivance whereby the same carriage may in a few minutes, be changed by the driver into two complete tip-carts of the common

dimensions, and applicable to all the uses of carts in general, or into one waggon, so complete, that a narrow inspection is necessary to distinguish it from a common waggon. The carts have a contrivance (a) to render them more safe and easy to the horses in going down a hill, and have movable side-ladders (b b), which will be found of great use in carrying corn, bark, &c. It may be constructed with perfect facility by the wheelwrights of any county its shape and particular dimensions can be suited to the wishes of the owner, or to the local fashion of his neighbourhood. The result of considerable experience and enquiries enables its inventor to state, that it may, in any county, be completed for about five pounds more than the cost of two common carts. It must, however, be admitted to be somewhat more clumsy than a common waggon.

2771. *Gordon's one-horse waggon* (fig 397) is a very scientifically designed machine. The wheels are cylindrical, and of the breadth of six inches. The draught is by what is called a draught spring. (fig. 398.) "By these draught springs," the inventor says, "a carriage will be put into motion by little more than half of the power that would be necessary without them, and the benefit will continue during all the time that the carriage may be continued in motion, but the benefit will be lessened as the speed of

the carriage may be increased, the projectiles or forward force being increased in and

397

of it. Tugs, which are the greatest cause of the restiveness of horses, are prevented by these springs, and jolts are very much lessened and carriages and

horses will not be so soon worn out and the motion of carriages will be much easier

When several beasts are employed to draw any carriage, each should be attached by one of these springs. The advantage is said to be obtained by the spring being squeezed together in some degree, before the carriage can be set in motion and the exertion of the spring to expand itself pulls the carriage with so much force, which is added to the force exerted by the beast. Sir Alexander Gordon, the inventor, is said to have employed carriages of this sort himself but they have never come into general use. Messrs. Morton of Leith Walk perfectly understand their construction, and their details are recorded in the *Farmer's Magazine* vols. xvii. and xx.

2772 Light waggons drawn by one horse are recommended for general use where roads are hard and smooth, and not hilly. Mr Stuart Menteth uses them at Closeburn in Dumfriesshire and frequently draws from a ton and a half to two tons in a waggon weighing not more than nine cwt. drawn by one horse.

#### SECT. VIII. Machines for threshing and otherwise preparing Corn for Market.

398

\* 2773 Threshing and preparatory machines include threshing and winnowing machines, and awn and smut machines. Threshing machines are common in every part of Scotland, on

farms where the extent of tillage-land requires two or more ploughs and they are every year spreading more extensively in England and Ireland. They are worked by horses, water wind, and, of late, by steam, and their powers and dimensions are adapted to the various sizes of farms. Water is by far the best power but, as a supply cannot be obtained in many situations, and as wind and steam require too much expense for most farms, horses are employed more generally than any other. Where windmills are erected, it is found necessary to add such machinery as may allow them to be worked by horses, occasionally in very calm weather, and the use of steam must be confined, for the most part, to the coal districts.

2774 The operation of separating the grain from the straw was long performed by the flail, to the manifest injury of both the farmer and the community for though in some cases the work was tolerably well performed, yet in a great majority of instances it was otherwise. A quantity perhaps equal to the average of the seed sown, was lost even in the best cases but, where the allowance to the thresher was either a proportion of the produce, known by the name of lot, generally a twenty fifth part or when he was paid in money, at so much per boll the temptation to do the work in a slovenly manner was so great, that a quantity perhaps double what was required for seed, was lost upon many farms — an evil that did not escape the notice of intelligent men, by several of whom attempts were made to invent something that would do the work more perfectly this, therefore, seems to have led to the construction and use of this valuable machine.

2775 The first threshing-machine, as before observed (735) was invented by Menzies, brother to the then sheriff-depute of East Lothian the machinery was driven by a water wheel, which put in motion a number of flails, of the same kind with those used in threshing by the hand. Trials made with these machines were so far satisfactory that a great deal of work was done in a given time; but, owing to the velocity required to do the work perfectly they soon broke, and the invention fell into disrepute.

2776 Another attempt, some time in the year 1768, was made by a farmer in the parish of Dumblane in Perthshire. His machine was constructed upon principles similar to the flail mill, having an upright shaft with four arms enclosed in a cylinder three and a half feet in height and eight in diameter within which the shaft and its arms were turned with considerable velocity by a water-wheel. The sheaves, being presented by the hand, were let down from the top upon the arms by which the grain was beat out, and, together with the straw descended through an opening in the floor, where they were separated by ridges and flannels, also turned by the water-wheel.

2777 A third attempt, about twenty years after, was made by Elderton, near Alnwick, and Beart, at Work, both nearly about the same time. Their machine was so constructed as to act by rubbing, in place of beating out the grain. The sheaves were carried between an indented drum, seven six feet in diameter and a number of rollers of the same description ranged around it, towards which they were pressed by springs, in such a way as to rub out the grain when the drum was turned round. Upon trial, this machine was also found inefficient, as alone with its doing very little work in a given time, it bruised the grain, and so materially hurt its appearance as to lessen its value considerably in the market.

2770. The machine, in its then imperfect state, was seen by the late Sir Francis Kinkel Bart. of Glendaloch, a gentleman well acquainted with mechanics, and who had paid much attention to country affairs: he advised to him that the machine might be rendered more perfect by enclosing the drum in a stout cover, and fixing on the outside of it four staked pieces of wood, capable of being raised a little from the circumference by springs, in such a way as to press against the staked cover, and to rub out the grain as the sheaves passed between them. But, after repeated trials, it was found to bruise the grain nearly as much as the method from which it was copied. In that state it remained for some time, and was afterwards used by Sir Thomas to a very speedy and ingenious character. Melkio of Know Mill, in his neighbourhood, a millwright by profession, who held for a very considerable time employed his thoughts upon the same subject. After much consideration, and several trials, it appeared to Melkio that the purpose of separating the grain from the straw might be accomplished upon a principle different from any that had hitherto been attempted, namely by shrouding upon the sheaves by their velocity and beating out the grain, in place of pressing or rubbing it out; accordingly a model was constructed at Know Mill, in which the grain was beat out by the drum, in which it was presented through two plain feeding-rollers, which were afterwards altered for fluted ones. The first machine on a large scale, executed upon this principle, was done by a son of Melkio's, Mr Stein of Kibbale, in the year 1785, which, when finished, performed the work to the satisfaction of all parties, and established Melkio's principle of beating out the corn as superior to all others. This superiority it still maintains and is likely ever to do so.

2771. Many improvements have been made on these machines since their introduction. One of the most useful of these, perhaps, is the method of delivering the straw, after it has been separated from the corn by the circular roller, to what is called a *travelling-shaker* which carries it to the straw-barn. This shaker, which revolves like the endless web used in cotton and other machinery is composed of small rods, placed so near as to prevent the straw from falling through while any thrashed corn that may not have been formerly separated, drops from it in its progress, instead of falling along with it, where it would be trodden down and lost.

2772. Improved mode of yoking the horses. It is well known that the work of horses in threshing-mills is unusually severe, if continued for any length of time; that they sometimes draw unequally that they as well as the machine itself are much injured by sudden jerks and strains which are almost unavoidable, and that, from this irregularity in the impelling power, it requires much care in the man who presents the corn to the rollers to prevent bad threshing. It is therefore highly desirable that the labour should be equalized among the horses, and the movements of the machine rendered as steady as possible. A method of yoking the horses in such a manner as compels each of them to take his proper share of the labour has accordingly been lately introduced, and the necessary apparatus, which is neither complicated nor expensive, can be added to any machine worked by animal power. (*Farmer's Magazine* vol. xiii. p. 579 (1794 and 1795, and, figs. 393, 394, and 400.)

2773. *Winnowing machines edited.* All well constructed threshing mills have one winnowing machine, which separates the chaff from the corn before it reaches the ground, and a second sometimes receives it from the first, and gives it out ready for market, or nearly so. If the height of the building does not admit of this last addition, a separate winnowing machine, when the mill is of great power is driven by a belt from it. In either of these ways there is a considerable saving of manual labour.

2774. *Advantages of threshing machines.* With a powerful water-mill, the editor of *The Farmer's Magazine* observes, it cannot be doubted, that corn is threshed and dressed at no more expense than must be incurred for dressing alone when threshed with the flail. Besides, the corn is more completely detached from the straw, and, by being threshed expeditiously a good deal of it may be preserved in a bad season which would have spoiled in a stack. The great advantage of transferring forty or fifty quarters of grain in a few hours, and under the eye of the owner from the yard to the granary or market, is of itself sufficient to recommend this invaluable machine, even though there were no saving of expense.

2775. *The specific advantages resulting from the use of the threshing machine are thus stated in The Code of Agriculture.* 1. From the superiority of this mode, one twentieth part more corn is gained from the same quantity of straw than by the old-fashioned method. 2. The work is done more expeditiously. 3. Filthiness is avoided. 4. The grain is less subject to injury. 5. Seed corn can be procured without difficulty from the new crops, for those to be sown. 6. The market may be supplied with grain more quickly in times of scarcity. 7. The straw, cutted by the mill, is more useful for feeding cattle. 8. If a stack of corn be heated it may be threshed in a day and the grain, if kiln-dried, will be preserved and rendered fit for use. 9. The threshing-mill lessens the injury from smutty grain, the balls of smut not being broken, as when beaten by the flail, and, 10. By the same machine the grain may be separated from the chaff and small seeds, as well as from the straw. Before the invention of threshing-mills farmers and labourers endured much drudgery, the large corn farmers sustained much damage from bad threshing; and had much trouble, vexation, and loss, from careless and wicked servants; but now since the introduction of this valuable machine, all his difficulties, in these respects, are obviated.

2776. The advantage that might be derived by the public were threshing mills used in every case for separating corn from the straw is thus estimated by Brown of Marble:—

The number of acres producing grain in Great Britain, at	8,000,000	one twentieth part of the produce, or in quarters,	1,800,000
The average produce in quarters, at 3 qrs. per acre,	24,000,000	The value of that increased quantity at 40s. per quarter	18,400,000
The increased quantity of qrs. in produce by threshing-mills, found of being the 2d, 3		The saving in the expense of labour at 1s. per quarter	21,800,000

2785. A variety of *thrashing machines* have been made in England, both on the rubbing and beating, or scutching, principle, and some combining both modes but none have been found to answer the purpose of separating the grain from the straw as well as those of Melkio, which is the kind exclusively used in Scotland and the north of England.

2786. *Melkio's two-horse threshing machine, with the new improved yoking apparatus* (figs. 399. and 400.), is the smallest use of horse engine which is made. From the levers, or hanging pieces (a), by which the cattle draw when working this machine, proceed the chains or ropes to which the horses are yoked, these chains or ropes being united by an iron frame, placed upon a lever, having liberty to turn on a bolt; one end of each of two single ropes is fixed to this iron frame, and upon their other ends are fixed small blocks; in each of which is placed a running sheave, and over these sheaves pass double ropes or chains. One horse is yoked to these chains at the one arm, and one at the other arm, so that the chains or ropes by which they draw being connected by the blocks, and the sheaves having liberty to move either way, if one of the horses relaxes, immediately the other presses the collar to his shoulder. For instance, if the horse yoked to the chains at one arm (fig. 400. a) were to relax, then the one yoked at the other (b) would instantly take up his rope, and pull the collar hard to his shoulder,

so that the lazy horse must either exert himself or be drawn backward, until the hooks, to which he is yoked, rest on the timbers. Thus each horse spurs up his fellow, they being

both connected by the ropes and sheeves their exertions are united, so as to form one power applied to the machine, instead of two powers, independent of one another. By this

means the draught will always press the collars equally upon the horses shoulders, and though they are working in a circle yet the strains of the draught must press fairly or equally, on their shoulders, without tainting their bodies to either side. This advantage cannot be obtained in the common way of yoking horses in a threshing machine, unless the draught-chains on each side of the horse be made in exact proportion in length to the diameter of the circle in which he walks, or the chain next to the centre of the walk be made a little shorter than the one farthest from it, which is often neglected, but in this way of yoking the horses, the strain of the draught will naturally press equally on his shoulders when pulling which of course must be less severe on the animal when walking in a circle.

1787 The advantages of this method of yoking horses to a threshing machine, which was invented by Walter Samuel, blacksmith at Niddry in the county of Linlithgow, have been fully ascertained by experience, and acknowledged by the most intelligent farmers in Scotland. They are as follows —

1st. The very great comparative ease obtained for the cattle, in this the heaviest part of their work. This, without doubt, is a real saving of labour, for it is no exaggeration to affirm, that five horses, yoked by this apparatus to a threshing machine, will perform with equal ease the labour of six horses, of equal strength and weight, yoked in the common way, each horse being independent of the rest.

2dly A very great saving results in the tear and wear of the machine, from the regularity and uni-

terity of the movement. This will be acknowledged by any judge of the subject who witnesses the performance. The sudden jerks and strains that generally take place in the usual way are found to be quite unneeded; the machinery moving with the same kind of uniformity as if driven by water. In some seasons of which the work is better performed, and that in a very perceptible degree.

2788. *Mellie's water threshing-machine* (fig. 401) is the

preferable engine, when a supply of water can be obtained. The main axle or shaft (a), upon which is fixed the water-wheel (b), has placed upon its circumference cast-metal segments (c), the teeth of which turn the pinion which is fastened on the axle of the threshing-drum; the platform, on which the unthreshed corn is spread, joins the feeding rollers, that conduct the corn forward to the threshers next the threshing-drum is the straw-shaker driven by a leather belt, passing over a sheave, fixed on an iron spindle connected with the axle of the water-wheel and the sheave on the axle of the shaker.

2789. *Mellie's threshing machine to be driven by water or by four horses* (fig. 402.), is a powerful and convenient engine, as advantage may be taken of water when it is

abundant, and in dry seasons horses can be applied. To this machine the improved apparatus for yoking the horses is appended, and by the simple operation of varying the positions of the pinions on the common shaft (a), which communicates with the water and horse-wheel (b, c), threshing may be carried on without interruption, either with the water or the horses separately, or a small quantity of water may be applied to assist the horses at any time, when a sufficient supply of water cannot be obtained to impel the machine alone.

2790. *Mellie's threshing machine to be driven either by wind or six horses* (Gray, Pl. XII) is a powerful but costly erection. On large corn farms, however, it will answer to erect such machines; and there are frequent instances in Berwickshire and Northumberland, of farmers incurring that expense on the security of twenty-one years' leases. The machinery of the wind power of this machine is fitted up with a small van to turn the large ones to face the wind, and with the machinery necessary to roll on or off the sails according to its increase or diminution; by which means the naturally unsteady power of wind is rendered as regular as that of horses or water. The threshing part of this machine contains the usual apparatus, and also a complete set of fanners and screens for cleaning the corn. To the board upon which the unthreshed grain is spread, and introduced between the feeding rollers, succeeds the drum, with the threshers, or beaters, fixed upon the extremity of its arms, then the shaker, that receives the straw from the threshing drum, and conveys it to the second shaker, by which it is thrown down a sloping scarse, either on the low floor, or upon a sparred rack, which moves on rollers, turned by the machine, and by this means is conveyed into the straw-shed, or else into the barn yard. One scarse is placed below the threshing-drum; and, while the drum's circular motion throws out the straw into the straw-shaker which conveys it to the second shaker, the chaff and grain pass at the same

thrust down through a canvas or sparged rack into the hopper, which conveys it into the fanners. By the fanners the corn is separated from the chaff, the clean grain running out at the opening, and the chaff or any light refuse blowing out at the end by the rapid motion of the fans, which are driven by a band or rope from a sheave placed upon the axle of the threshing-drum, and passing over the sheave fixed upon the pivot of the fans.

2791 *Meikle's threshing machine to be impelled by steam* is the same arrangement of interior machinery, with a steam engine outside of the barn connected by a shaft in the manner of the wind and water machines.

2792. *Portable threshing-machines*, to be fixed in any barn, or in the open field, for threshing the crops of small farms, or for other purposes of convenience, are differently contrived. Except the hand machine, already described (§ 2646.), all of them work by horses, and generally by one, or at most two. The most complete have a large frame of separating beams, into which the gudgeons of the larger wheels work, and which retains the whole of the machinery in place. In general there are no fanners but sometimes a winnowing machine is driven by a rope from the threshing machinery. Such machines are considerably more expensive, in proportion to their power, than fixed machines: they are, therefore, not much used, and indeed their place might often be profitably supplied by the hand machine. Portable threshing machines are very common in Suffolk. It is not unusual in that county, for an industrious labourer who may have saved 80*l.* or 40*l.* to own one, which is moved from place to place on two wheels, and worked, when fixed, by three or four horses. The horses and other labourers are supplied by the farmer, and the owner of the machine acts as feeder. The quantity threshed is from fifteen to twenty quarters a day. Reaping machines, and steam ploughing-machines, will probably in a few years be owned, and let out for hire in a similar manner.

2793. *Wear's portable two-horse power threshing machine* is one of the best in England. The corn is threshed on Meikle's skutching principle, and is sometimes supplied by fluted rollers, and sometimes introduced through a hopper directly over the drum, a mode which is found not to break the straw so much as the common mode.

2794. *Lester's portable threshing-machine* received the straw without the intervention of rollers, and separated the corn entirely by rubbing. It was an ingenious, but very imperfect, machine, and never came into use.

2795. *Forrest or Shifnal's portable threshing machines* have been employed in several parts of Warwickshire, Shropshire, and the adjoining counties. It combines the rubbing and skutching methods, but does not perform either perfectly. Meikle's machines, in fact, can alone be depended on, for completely separating the grain from the straw, though some others may render the straw less ineligible for thatch, or for gratifying the present taste in litter of the London grooms.

2796. *The smut machine* (fig. 403.) is the invention of Hall, late of Ewel in Surrey,

now of the Prairie in the United States. It resembles that used for dressing flour, and consists of a cylinder perforated with small holes, in the inside of which are a number of brushes, which are driven round with great rapidity. The wheat infected with smut is put into the cylinder by a hopper (a) and the constant friction occasioned by the rapid motion of the brushes (b) effectually separates the smutty grain, which is driven out by the holes of the cylinder. Hall finds that it requires much more power to clean wheat by this machine, than to dress flour. A machine on this construction might be a very useful appendage to every threshing machine, for the purpose of effectually cleaning all wheat intended for seed, or such wheat, meant for the market, as had a great proportion of smut in it. (*Stratton's Surrey*, p. 141.)

\*2797. *Mitchell's hummelling machine* (fig. 404.) is the invention of a millwright of that name in the neighbourhood of Elgin, and it has been very generally added to threshing machines, in the barley districts of Scotland, for the purpose of separating the awns from the grains of barley. It operates on the scutching principle, and is composed of a scutcher consisting of a spindle, at the top of which is fixed a wheel for putting it in motion, and between this wheel and its lower extremity three tier of scutching arms (a); each scutcher is composed of two pieces forming a cross (b), and bevelled at the edges to prevent them from cutting the barley in the operation of hummelling (c). The scutcher revolves in a cylinder (d), into which the barley passes through a spout (e) from a hopper placed over the machine. The cylinder may either be of wood or cast iron, and the frame.

stick which supports it (*f*) may be of either, or of both of these metals. (*Farm. Mag.* vol. xlii.)

2798. To take the awns from barley where a threshing machine is used, a notched spar, lined on one side with plate iron, and just the length of the rollers, is fixed by a screw bolt at each end of the inside of the cover of the drum, about the middle of it, so that the edge of the notched stick is about one eighth of an inch from the arms of the drum as it goes round. Two minutes are sufficient to put it on, when its operation is wanted, which is, when putting through the barley the second time, and it is as easily taken off. It rubs off the awns completely.

2799. A cheap method of hummelling barley, where a threshing machine is in use, consists in having a second cover for the drum lined with tin, having small holes perforated in it in the manner of a grater, and the rough side externally. The grain being separated from the straw in the ordinary way the grated cover is to be substituted for the common one, and the grain passed through a second time. This mode is said to succeed as well as any other (*Farm Mag.* vol. xiii. p. 443.)

405

2800 Hand hummelling machines (figs. 405. and 406.) are in use in Lincolnshire and other parts of England, where barley is much cultivated, and where threshing machines are little in use. (*Gard. Mag.* vol. v.)

406

#### Sect. IX. Mechanical and other fixed Apparatus, for the Preparation of Food for Cattle, and for grinding Manure.

2801 The principal food-preparing contrivances are, the steamer, boiler, roaster, breaker or bruiser, and grinder.

\*2802 An apparatus for steaming food for cattle, the editor of *The Farmer's Magazine* observes, should be considered a necessary appendage to every arable and dairy farm of a moderate size. The advantage of preparing different sorts of roots, as well as even grain, chaff, and hay by means of steaming apparatus, for the nourishment of cattle, begins now to be generally understood. It has been long known that many sorts of roots, and particularly the potato, become much more valuable by undergoing this sort of preparation and it is equally well known that when thus prepared they have been employed alone as a substitute for hay, and with cut chaff, both for hay and corn, in the feeding of horses, as well as of other animals. To a farmer who keeps many horses or cattle, or even swine or poultry, the practice of boiling their feed in steam is so great a saving and advantage, that it deserves the most particular attention. Though potatoes have often been given raw to both horses and cattle, they are found to be infinitely preferable when cooked by steam, as they are rendered thereby much drier and more nutritive, and better than when boiled in water; this has been long since shown by the experiments of Wakefield of Liverpool, who, in order to ascertain it, fed some of his horses on steamed and some on raw potatoes, and soon found the horses fed on the steamed potatoes had greatly the advantage in every respect. These on the steamed potatoes looked perfectly smooth and sleek,

while the others were quite rough. Eckstein also found them useful instead of corn; and the extensive and accurate trials of Curwen have placed the utility and advantage of them in this way beyond all dispute. Curwen has found that in their preparation in this way the waste of the potato is about one eighteenth part, and that straw when given along with them answers as well as hay, as the horses keep their condition and do their work equally well.

2803. *A steaming apparatus on a grand scale* has been erected at Worthington, by Curwen, of which an accurate ground plan and section, with a copious description, are given in *The Complete Farmer*. One erected by the Duke of Portland, chiefly for steaming hay, will be afterwards described.

2804. *An economical steaming and washing machine* has been described by Grey, in his *Implements of Husbandry, &c.* The parts of this machine are few and simple: the potatoes are washed, and emptied into a large chest to drip, and when a sufficient quantity is washed, this chest, by a motion of the crane, empties itself into a steaming-box, placed almost immediately over the boiler; by which means a large quantity of potatoes or other materials are steamed at once. The chief advantage attending the use of this simple steaming apparatus, he says, consists in saving manual labour in lifting on and off the tubs for holding the potatoes, or other materials to be steamed, also in lessening the expense of erection, and repairs of leaden or copper pipes, turn-cocks, &c. Its superiority over one with a number of steaming-tubs, especially in a large operation, will be at once perceived by those who have paid attention to the subject. The steaming boiler may be made of any approved form, and of a size proportioned to the steaming-box, with a furnace of that construction which affords the greatest quantity of heat to the boiler with the smallest waste of fuel. The steaming-box may be made either of cast-metal plates, enclosed in a wooden frame, or of stout planks, well joined, and firmly fixed together. It has been found by experience, that a box, eight feet in length, five feet wide, and three feet deep will serve for cooking, in the space of one hour with the attendance of one person, a sufficient quantity of potatoes to feed fifty ordinary horses, allowing each horse thirty two pounds weight per day. The boiler and steaming-box, however, ought to be made of a size in proportion to the number of cattle to be fed, or the quantity of materials to be steamed. Both boiler and steaming-box may be made of any form and proportion that will best answer the intended purpose, with the least expense.

2805. *A steaming-machine, on a simple and economical plan* (fig 407), consists of a boiler, and wooden chest or box placed over or near it. The box may be of any size, and so placed as to be supplied and emptied by means of wheel or hand barrows in the easiest manner, either by the end or top, or both, being made to open. If the box is made eight feet by five, and three deep, it will hold as many potatoes as will feed fifty cows for twenty-four hours, and these may be

steamed in an hour (*F Mag* vol xviii. p. 74.)

2806. *Boilers or boiling machines* are only had recourse to in the case of very small establishments. By means of fixed boilers, or boilers suspended by cranes, on the Lodi dairy principles (370) roots may be boiled, and chaff, weak corn, and other barn refuse, rendered more palatable and nutritive to cattle. Hay tea also may be made, which is a salutary and nutritive drink for horses or cattle when unwell, or for calving cows. Food for swine and poultry may also be prepared in this way: or water boiled and salted to half prepare chaff and culmiferous plants for animals.

2807. *A baking or roasting oven* has been recommended for preparing the potato by Fiorrepont (*Comm. Board of Agr* vol. iv), which he states to be attended with superior advantages but as, independently of other considerations, the use of such an oven must be limited to potatoes, a steaming-machine, which will prepare any sort of food, is undoubtedly preferable for general purposes. Many speculative plans of this sort, however ingenious, chiefly deserve notice as bescons to be avoided, or to prevent their being invented and described a second time.

2808. *A machine for pounding limestone* (fig 408.) is in use in some parts of the country where unburnt chalk, limestone, or limestone gravel, is used as a manure. This machine may be worked by steam, wind, water, or the power of horses. It consists of a beam (a) working on a wheel (b) and raising and lowering a cone of cast iron (c). The base of this cone, which may be a circle of from two to six feet in diameter, according to the power of the machinery, and the size and hardness of the material to be broken, should be studded with knobs or protuberances about two inches long, of a diamond shape, terminating in a blunt point, and about five inches in circumference at the

bottom. The stones to be broken are laid on a circular segment, founded at some depth below the surface, the foundation of which is prepared in the following manner:— "A stratum is formed of clay, well tempered, and mixed with a proportion of burnt limestone, powdered without being sieved, and forge ashes beat very small. When this is properly dried, a bed of sand, about eighteen inches in thickness, should be laid above it, and paved with common paving stones of the kind used for streets; this, after being well beat down, should be covered with another bed of sand of the same thickness, which should be paved in the same manner, and afterwards well beat down. The foundation of the building should be, at least, six feet below the common surface which will allow eighteen inches for the clay, thirty-six inches for the two beds of sand, and eighteen inches for the two courses of pavement. The circumference should consist entirely of hewn stone, at least the uppermost three feet of it the stones of which should be strongly battled together with iron, and secured on the outside with numerous wooden posts driven into the earth, and different courses of pavement, extending at least six feet all round, carefully laid, and well beat down. A floor prepared in this manner, if it is not used too soon, will resist any force that can be let fall upon it. The foundation laid into it should not be too small, and should have a light bedding of sand in the soil to give it stability" (*Form. Mag.* vol. in.)

2809. A stone-levelling machine to be impelled by steam has lately been invented by Mr James Milne of Edinburgh. It is said to save an immensity of manual labour, and to be competent to the execution of the finest mouldings. (*Scottishman*, Oct. 28 1839.)

2810. *Lea's Machine for raising large stones* (fig. 409) is a powerful engine. An iron plug is driven into the stone, and retained there by its elasticity. The machine "is placed over the stone to be raised, by extending the posts on each side, and then the windlass is attached. Of the stone to be thus raised, however large it be, it is enough to see the smallest part appear above the surface of the ground. At this part, let a workman, with a mallet, and the common steel-boring chisel of masons, make a small circular hole, about two inches deep, and as perpendicular as possible. This chisel should be of such a size as to make the

hole about a sixteenth part of an inch less in diameter than the plug itself, so that a stroke or two of a hammer may be necessary to drive the iron home. When the latter is thus driven an inch, more or less, into the stone, it is attached to the block, and the ropes are tightened by turning the winch. Nothing more is now requisite than to set as many persons as may be required to work the windlass, and, strange as it will seem, with no other fastening than this simple plug, the heaviest mass will be torn up through every opposing obstacle." (*Quar Jour Agr.* vol. i. p. 206.)

### CHAP. III.

#### *Edifices in use in Agriculture.*

\*2811. A variety of buildings are necessary for carrying on the business of field culture: the nature and construction of which must obviously be different, according to the kind of farm for which they are intended. Suitable buildings, the editor of *The Farmer's Magazine* observes, are scarcely less necessary to the husbandman than implements and machinery; and might, without much impropriety, be classed along with them, and considered as one great stationary machine, operating more or less on every branch of labour and produce. There is nothing which marks more decidedly the state of agriculture in any district, than the plan and execution of these buildings.

2812. *In erecting a farmery, the first thing that deserves notice is its situation, both in regard to the other parts of the farm, and the convenience of the buildings themselves. In general, it must be of importance on a noble farm, that the buildings should be set down at nearly an equal distance from the extremities or so situated, that the access from all the different fields should be easy, and the distance from those most remote, no greater than the size of the farm renders unavoidable. The advantages of such a position in saving labour are too obvious to require illustration and yet this matter is not near so much attended to as its importance deserves. In some cases, however, it is advisable to depart from this general rule, of which one of the most obvious is, where the command of water for a threshing-mill, or other purposes, can be better secured in another quarter of the farm.*

2813. *The form most generally approved for a set of offices is a square, or rather a rectangular parallelogram; the houses being arranged on the north, east, and west sides, and the south side fenced by a stone wall, to which low buildings, for calves, pigs, poultry, &c. are sometimes attached. The space thus enclosed is usually allotted to young cattle; these have access to the sheds on one or two sides, and are kept separate, according to their size or age, by one partition-wall or more. The farmer's dwelling-house stands at a short distance from the offices, and frequently commands a view of the inside of the square and cottages for servants and labourers are placed on some convenient spot, not far from the other buildings.*

2814. *The different buildings required for the occupation of land are chiefly those devoted to live stock, as the stable, cow-house, cattle sheds, &c. those used as repositories or for conducting operations, as the cart-shed, barn, &c., and human habitations, or cottages and farm-houses. After noticing the separate construction of these edifices, we shall exemplify their combination in different descriptions of farmeries.*

#### SECT. I. Buildings for Live Stock.

2815. *Buildings for agricultural live stock are the stable, cow-house, cattle-houses and cattle-sheds, sheep-houses, pigsties, poultry-houses, rabbitry pigeonry and bee-house.*

2816. *The stable is an important building in most farmeries it is in general placed in the west side of the square with its doors and windows opening to the east. Nothing conduces more to the health of horses than good and wholesome air. The situation of the stable should always be on firm, dry and hard ground, that in winter the horse may go out and come in clean, and, where possible, be built rather on an ascent, that the urine and other liquid matters may be easily conveyed away by means of drains for the purpose. As there is no animal that delights more in cleanliness than the horse, or that more dislikes bad smells, care should be taken that there be no hen-roost, hogsties, or necessary houses near the place where the stable is to built. The swallowing of feathers, which is very apt to happen, when hen-roosts are near often proves injurious to horses. The walls of a stable ought to be of brick rather than stone, and should be made of a moderate thickness, two bricks or a brick and a half at least, or the walls may be built hollow, not only for economy but for the sake of warmth in the winter and to keep out the heat in the summer. The windows should be proportioned in number to the extent, and made on the east or north side of the building, that the north wind may be let in to cool the stables in the summer, and the rising sun all the year round, especially in winter. They should either be washed or have large casements for the sake of letting in air enough and there should always be close wooden shutters, turning on bolts, that the light may be shut out at pleasure. Many pave the whole stable with stone, but that part which the horse is to lie on is often boarded with oak planks, which should be laid as even as possible, and cross-wise rather than length-wise and there should be several holes bored through them to receive the urine and carry it off underneath the floor by gutters into one common receptacle. The ground behind should be raised to a level with the planks, and be paved with small pebbles. There are mostly two rings placed on each side of the manger, or stall, for the reins of the horse a halter to run through, and a logger is to be fixed to the ends of these, sufficient to pass them perpendicularly but not so heavy as to tire the horse, or to hinder him from eating, the best place for him to eat his corn in, is a drawer or locker, which need not be large, so that it may be taken out at pleasure to clean it, by which means the common dirtiness of a fixed manger may be avoided. Many people are against having a rack in their stables, they give the horse his hay in a trough bin, formed of boards with an open bottom.*

2817. *A lofty stable is recommended by White (Treatise on Feter Med. p. 1), fifteen or twenty but never less than twelve feet high, with an opening in the ceiling for ventilation. The floor he prefers is brick or limestone, inclining not more from the manger to the gutter than an inch in a yard. Some lister he says, should always be allowed for a horse to stale upon, which should be swept away as often as is necessary. This, with a pail or two of water thrown upon the floor, and swept off while the horse is at exercise, will keep the stable perfectly clean, and free from offensive smells.*

2518. The depth of a stable should never be less than twenty feet, nor the height less than twelve. The width of a stall should not be less than six feet clear. But when there is sufficient room, it is a much better plan to allow each horse a space of ten or twelve feet, where he may be loose and exercise himself a little. This will be an effective means of preventing scalds, and a great relief to horses that are worked hard. With respect to the rack and manger, white pasture the summer on the ground, rising three feet high, eighteen inches deep from front to back, and four feet long. The manger, eighteen inches deep, eighteen inches from front to back, and five feet in length. The rack, be better being closed in front, than being open. It opens, allowing that horses when lying down will thus be enabled to eat if they choose. A close-fronted rack, however, is better adapted for saving hay. The back part of the rack should be an inclined plane made of wood, should be gradually sloped towards the front, and should terminate about two feet down. Such a rack will hold more hay than ever ought to be put before one horse. The advantages of this rack are numerous. At the first place, the hay is easily put into it, and it remains a dry lot over the stable unnecessary, which ought to be an inducement to the builder to make the stable as lofty as it ought to be, to obtain proper ventilation. All the hay that is put into the manger will be eaten; but in the common rack it is well known that a large portion of the hay is often pulled down upon the litter and trodden upon, whereby a considerable quantity is often wasted. It prevents the hay-seeds or dust from falling upon the horse, or into his eyes, and what is of considerable importance, though seldom attended to, there will be an inducement to the horse-keeper to give the horse hay in small quantities at a time, and frequently, from the little trouble which attends putting it into the rack. The saving in hay that may be effected by the use of this rack is so apparent, that it need not be dwelt upon. A great saving also may be made in oats, by so fastening the horse's head during the time of feeding, that he cannot throw any of them out of the manger. This kind of rack and manger, from being boarded up in front, will effectually prevent the litter from being kept constantly under the horse's head and eyes, by which he is compelled to breathe the vapours which arise from it. It will also prevent him from getting his head under the manger, as sometimes happens, by which means, not infrequently, the poll evil is produced. The length of the halter should be only four feet from the head-stall to the ring through which it passes: this will admit of his lying down with ease, and that is all which is required. The ring should be placed close to that side where the manger is, and not in the centre of the stall. The side of the stall should be sufficiently high and deep to prevent horses from sitting and kicking each other. When the common rack and manger are preferred, the rack-staves should be perpendicular, and brought nearly down to the manger, and thus may easily be done without the necessity of a hay loft, and the manger may be made deep and wide as described.

2519. The window of the stable should be at the south east end, and the door at the opposite end. The window should be as high as the ceiling will admit of, and in size proportioned to that of the stable. In one of twelve feet high, it need not come down more than four feet, and it will then be eight feet from the ground, and out of the way of being broken. The frame of the window should be moveable upon a pin at its centre, and opened by means of a cord running over a pulley in the ceiling, and fastened by means of another cord. With a window of this kind, in a stable of three or four horses, no other ventilation will be required: a person never need be solicitous about finding openings for the air to enter where there is sufficient room above, and means for it to escape. A stable thus constructed will be found conducive to the health and comfort of horses, and will afford an inducement to the horse-keeper to attend to every little circumstance which may contribute to cleanliness. He will not allow the smallest bit of dung to remain swept up at one end of the stable, as it commonly is. The pale should be kept outside, and not standing about the stable as they usually are. If it is necessary to take off the chill from water, it is much better, and more easily done by the addition of a little hot water, than by suffering it to stand in the stable, and while the horses are at exercise, the litter should be all turned out to dry, and the back floor well washed or swept out. A little fresh straw may then be placed for the horses to stifle upon. Litter thus dried during the day will serve again as well as fresh straw for the bottom of the bed, and be perfectly free from smell. The litter necessary to be kept under a horse that he may stifle with comfort, and without splashing himself is not considerable, and may be changed once a day. A great saving may be made in litter by turning it out, and drying it as described, and a shed built adjoining a stable would afford a place for doing this at all times, and might serve also to exercise and clean a horse in during wet weather.

2520. Neither dogs, cats, nor goats should ever be permitted to enter a stable, and dung should be kept at a distance from it. A good contrivance in cleaning horses is, to have two straps, one on each side of the stall, about one yard from the head of it. By these the horse may be fastened during the time he is cleaned, by which he will be effectually prevented from being the manger or the horse-keeper, and being kept back in the stall, the man will be better able to clean the front of his fore legs, chest, and neck, and be able to move round him. This is better than strapping him to the rack.

2521. Farm stables in Scotland, the editor of *The Farmer's Magazine* observes, are constructed in such a manner that all the horses stand in a line with their heads towards the same side-wall, instead of standing in two lines, fronting opposite walls, as formerly. Those lately erected are at least sixteen feet wide within walls, and sometimes eighteen, and the width of each stall upon the length of the stable is commonly five feet. To save a little room, stalls of nine feet are sometimes made to hold two horses, and in that case, the manger and the width of the stall are divided into equal parts by what is called a half trevice, or a partition about half the depth of that which separates one stall from another. By this contrivance, each horse indeed eats his food by himself, but the expense of angle stalls is more than compensated by the greater ease, security and comfort of the horses. The trevices or partitions which divide the stalls, are of deal two inches thick and about five feet high, but at the head of the horse, the partition rises to the height of seven feet (Fig. 410 a), and the length of the stall is usually from seven to eight feet. In many cases the end stall has a door.

or frame of boards to fit in between it and the back wall (b) in order to secure food of any kind, a sack horse, a stall, or more and feed, &c.

2522. The manger (c) is generally continued the whole length of the stable. It is about nine inches deep, twelve inches wide at the top, and nine at the bottom, all inside measure, and is placed about two feet four inches from the ground. Staples or rings are fixed on the breast of the manger to which the horses are tied.

2523. The rack for holding their hay or straw is also commonly continued the whole length of the stable. It is formed of upright posts (d), connected by cross-rails at each end, and from two to two and a half feet in height. The rack is placed on the wall, about one foot and a half above the manger. The bottom slant close to the wall, and the top projecting outwards, but the best plan is to place it upright (e, e, e). The cross-rails are sometimes made round, and sunk into the cross-wall, and sometimes square. In a few stables lately built, the round cross-rails on a pivot, which facilitates the horse's access to

the hay, without requiring the interstices to be so wide as to permit him to draw it out in too large quantities.

9264. Immediately above the racks is an opening in the hay-loft, through which the racks are filled. When it is thought necessary this may be closed by boards moving on hinges.

9265. The racks in some of the best stables occupy one of the angles between the wall and trottoir, and form the quadrant of a circle. The spars are perpendicular and wider placed than in the hanging racks. The hay-seed falls into a box below instead of being dropped on the ground, or incommoding the eyes and ears of the horse.

9266. Behind the horses, and about nine feet from the front wall, is a gutter having a gentle declivity to the straw-yard or urine-pit. Allowing about a foot for this, there will remain a width of eight feet to the back wall, if the stable be eighteen feet wide; a part of which close to the wall, is occupied with corn-chests and places for harness.

9267. With a view to save both the hay and the seed it is an advantage to have the haystacks so near the stable as to admit of the hay being thrown at once upon the loft. In some stables there is no loft, and the hay is stored in a separate apartment.

9268. The stable floor is, for the most part, paved with undressed stones; but in some instances, the space from the gutter to the back is laid with flags of freestone.

9269. Horse-hammels, or small sheds, with yards to each have been used as stables in a few instances, and with great success in Berwickshire. Each shed holds two horses, with a niche for their harness so each shed there is an open straw yard of small size, with a water trough, and a gate large enough to admit a cart to take out the dung. John Herriot, of Ladykirk, has long used these buildings for his horses with great success. He has lost none by death for a number of years, and they seldom have colds or any other disease. His horses lie in these open hammels in winter and it is remarked, that in frosty weather when snow is falling, and lying on the ground the animals do not go under cover but prefer to be out, with their backs and sides covered with snow. It is well known, that if a horse is kept out in winter he will have no grease, nor swelled legs, and perhaps few other diseases. These hammels seem to have all these advantages, at the same time that they protect the animal from damp, and prevent his back from being kept wet by heavy or long continued rains. Every farmer who keeps a large stock of horses, occasionally loses one by inflammation brought on by coughs and colds; but the horses of the farmer alluded to become aged and he has not had occasion to purchase a young horse for several years. (Herald of Scot. i. 28.) Suffolk cart horses lie out during night throughout the whole year; they are not exempt from grease, but they are probably more healthy than horses in general are.

9270. Cattle-sheds are used either for lodging milch cows, or for feeding cattle for the butcher. The principal requisites in buildings of this description are, to be capable of being well aired to be so constructed as to require the least possible labour in feeding the cattle and clearing away the dung and the stalls to be so formed as to keep the cattle as dry and clean as possible, with sufficient drains to carry away and reservoirs to collect the urine and dung. There are three ways in which the cattle are placed first, in a row towards one of the side walls, secondly, in two rows, either fronting each other with a passage between, or with their heads towards both side walls and, thirdly across, or upon the width of the house, in successive rows, with intervening passages for feeding and removing the dung. In the first mode, it is usual to have openings in the walls, through which the cattle are supplied with turnips otherwise they must necessarily be served from behind, with much inconvenience both to the cattle-feeder and the cattle themselves. The plan that is most approved, and now becoming general when new buildings are erected, is to fix the stakes to which the cattle are tied about two and a half or three feet from the wall, which allows the cattle-man, without going among them, to fill their troughs successively from his wheelbarrow or basket, with much ease and expedition. It is also a considerable improvement to keep the cattle separate, by partitions between every two. This will, in a great measure, prevent accidents, and secure the quiet animals from being injured by the vicious for in these double stalls each may be tied up to a stake placed near the partition, so as to be at some distance from his neighbours, and it is easy to lodge together such as are alike in size and in temper. The width of such stalls should not be less than seven feet and a half and the depth must be regulated by the size of the cattle.

9281. Cattle-hammels (fig. 411.)

The practice of feeding cattle in small sheds and straw yards, or what are called hammels in Berwickshire, deserves to be noticed with approbation when saving of expense is not a paramount object. Two cows are usually kept together and go loose in which way they are thought by some to thrive better than when tied to a stake, and at the same time, feed more at their ease than when a number are kept together as in the common straw yards. All that is necessary is, to run partition walls across the sheds and yards of the farmers; or if these are allotted to rearing stock one side of the square, separated by a cart-way from the straw yards, may be appropriated to these hammels. In the usual management of a row of cattle hammels in Berwickshire there is one hammel (a b) at one end used as a temporary repository for roots and straw for the cattle; then each hammel consists of the open yard (d e), and the covered part (c) the entrance door of which there is only one to each hammel, is in the wall of the yard (f) and on each side of it are two troughs (g h) for food, and a crib for hay or straw and for cut clover or other herbage in summer.

9282. Herriot's one-house at Glasgow contained two hundred cows. It stood upon a vaulted cellar, which was divided into three apartments: the middle one for the manure; that at one end for potatoes, and other rooms so be used as food; and in the other cows not giving milk were kept. The dung was dropped into the centre division through apertures in the gutters (fig. 412 a, c), eighteen inches in diameter covered with cast-iron plates. Sometimes a cart was brought into the cellar, and the dung as soon dropped into it, and carried away. The covers had flange-holes for lifting them up, and the dung was drawn along the grooves into them by a broad hoe or scraper fitted to the grooves. It was often found necessary to mix ashes with the dung, to render it of a fit consistency for being moved away. The second division of the vaults was fitted up for the process of distilling; darkness and quiet being considered favourable circumstances. In the third division roots were absolutely preserved from frost. At one end

of two cow-houses a tank was formed, fifty feet long, sixteen feet wide, and six deep, with its surface on a level with the bottom of the cellar; it was arched over, and had a man-hole for cleaning out the sediment, four feet in diameter, into this tank the waste of the urine was conducted, after being filtered through the urine gutters into spouts beneath it reaching the whole length of the house. Each filter consisted of a vessel covered with a plate of cast iron, pierced with small holes, the surface of the plate being on a level with the surface of the gutter: the use of the vessel under it is to receive the sediment, for which purpose it is made four inches wider than the cover and so this extra width the water runs over into the cast-iron spout by which it is conducted to the tank; it enters the tank by a division surrounded by boards pierced with holes, so as to filter it a second time, in order that the water may be pumped up with greater ease. This water was sold to the gardeners and others at from 1s. to 1s. 6d. per hundred gallons. The roof was supported in the middle by cast iron pillars (b) there were no ceilings, but the slates were hung

to the gables of the rafters on pins, with a good lap this being found warm enough in the coldest weather, and favourable for ventilation in the hottest. There were also windows in the roof, both for light and ventilation. The heat was generally kept to 80° or 85°. The passages (c) were paved, and five feet wide, and two inches and a half higher in the middle than at the sides.

2833. The floor on which the cows stood in Harley's cow-house was raised six inches above the passages; this not only showed the cows to greater advantage but kept them dry and clean and two and a half feet of the floor next to the trough were made of composition, similar to what is commonly used in making barn floors; because the principal weight of the cows being upon their fore feet, and as in lying down the whole weight is upon their knees, it was obviously desirable to have that part of the stall as smooth and soft as possible. Indeed, it is conceived that joints and flooring would be the best for that purpose, were it not for the expense. The back part of the stall was of hewn stone, and for about eighteen inches towards the groove there was an inclination of about half an inch, to let the water go off; these eighteen inches were of strict ashlar transverse, the strips being about an inch separate; this prevented the feet of the cows from slipping. In all cow-houses, perhaps the front part of the stall should be rather lower than the back part, since it would enable the cattle to lie easier; and, besides this, they would not be apt to slip their calf. Cows which put out their calf bed, or have a tendency to slip their calf, should have a straw mat laid below their hind quarters. The bottom of the feeding troughs was on a level with the floor of the stalls, both edges were of hewn stone, the outer one next the passage was three inches above the bottom of the trough and the other six inches higher. They were four inches and a half thick, and rounded to a semicircle the trough was one foot three inches wide, and six feet four inches long. (Harley's Dairy System, p. 54.)

2834. The standing room for the cows in the Harleian dairy, that is, the space between the feeding trough (d) and gutter (e), was from six to seven feet the latter dimension being for the larger cows. The breadth allowed for a cow was from three feet to three feet six inches two cows standing together between wooden partitions as in stables (f). Each cow is fixed to a stake nine inches from the partitions and six inches from the feeding trough; the stakes are two and a half inches in diameter and the cows are fixed to them by chains and swivels fixed to rings. "The chains were three feet seven inches long, consisting of twenty-one links, viz. three on one side of the swivel and eighteen on the other the short end of the chain had a hook for joining the chain with a broad point of an oval shape which was more easily hooked and unhooked, and answered the purpose better than the common mode used in dogs chains. The hooks, or racks for the hay are three feet two inches long, by one foot ten inches deep, framed with deal and fixed up with one horizontal and ten perpendicular iron rods a quarter of an inch in diameter. These hooks are hung with window cord which passes over pulleys, so that they can be raised by a wheel and passed at pleasure, so as to be above the heads of the cows, when they are eating green food from the feeding gutter. Mr. Harley considers it of importance that each cow should not only be kept clean by combing and brushing, but, by the chain system of fastening, should have the liberty of shaking its own skin and that of its fellow (Harleian Dairy System, p. 55.)

2835. Calf-pens, or calf-stages, are common additions to cow-houses, where the feeding of calves for the butcher is an object of pursuit. The principal thing to be observed in the construction of calf-pens is the laying of the floor,

which should be made of laths or spars about two inches broad, laid at the distance of an inch from each other upon joists, so as to make the floor about ten or twelve inches from the ground, as the situation will admit (Ag. 413.) This not only keeps them quite dry by allowing all the moisture to pass immediately away but has the advantage of admitting fresh air below the bedding, and thereby preventing that unwholesome disagreeable smell too often found among calves for it is to be understood, that this place below the floor (a) should frequently be cleaned, as well as the floor itself whenever it becomes wet or dirty; but it is not right to allow the litter to increase to a great thickness, otherwise the moisture will not so easily pass through. Calf-pens are, however, too often made without this spaced floor, and the fresh litter always laid on the old till the calves are removed, which is a slovenly practice and not by any means to be recommended. Stalls, or divisions, are too often neglected in calf-pens. Partitions, about three feet high, of thin deal nailed on small posts, might be so contrived as to be movable at pleasure, to increase or diminish the stall, if necessary, according to the age and size of the calf. If it be thought unnecessary to make the partitions movable, there might be a small round trough, in a circular frame, fixed in the corner of each pen, for holding the milk, and a door in the next adjoining corner. A small alight rack for holding a little hay placed at the upper part of the pen, might also be useful. The troughs should be round, that the calves may not hurt themselves upon them, which they might probably do on the angles if they were square. The advantages of this kind of calf-pens

are, that the calves are all kept separate in a small compass, and cannot hurt each other, as the stronger ones sometimes do the weaker when confined promiscuously, and their food may be much more easily and equally distributed.

5835. *The calf-pens in Glömsström, Marshal observes, are of an admirable construction; extremely simple, yet singularly well adapted to the object. Young calves, fattening calves more especially require to be kept narrowly confined; yokedness is, in a degree, essential to their thriving. A loose pen, or a long halter gives freedom to their natural fears, and a loose to their playfulness. Cleanliness, and a due degree of warmth, are likewise requisite in the right management of calves. A pen which holds seven, or consequently eight, calves, is of the following description.—The house, or roomstead, in which it is placed, measures twelve feet by eight. Four feet of its width are occupied by the stage, and one foot by a trough placed on its front, leaving three feet as a gangway into the middle of which the door opens. The floor of the stage is formed of laths, about two inches square lying the long way of the stage, and one inch asunder. The front fence is of staves, an inch and a half in diameter nine inches from middle to middle, and three feet high; entered at the bottom into the front bearer of the floor (from which cross-joints pass into the back wall) and studded at the top by a rail which as well as the bottom piece is entered at each end into the end wall. The holes in the upper rail are wide enough to permit the staves to be lifted up and taken out, to give admission to the calves; one of which is fastened to every second stave, by means of two rings of iron joined by a swivel one ring playing upon the stave, the other receiving a broad leathern collar buckled round the neck of the calf. The trough is for barley meal, chalk, &c. and to rest the pails on. Two calves drink out of one pail, putting their heads through between the staves. The height of the floor of the stage from the floor of the room is about one foot. It is thought to be wrong to hang it higher, lest, by the wind drawing under it, the calves should be too cold in severe weather: this, however might be easily prevented by litter or long straw dry thrust beneath it. It is observable that these stages are fit only for calves which are fed with the pail, not for calves which suck the cow.*

5837. *Hogsties, for the breeding or fattening of swine, are mostly built in a simple manner, requiring only warm dry places for the swine to lie in, with small areas before, and troughs to hold their food. They are generally constructed with shed-roofs, and seldom above six or seven feet wide, with height in proportion. In order that they may be convenient, they should be at no great distance from the house, and the less they are connected with the other farm-buildings the better. In some cases, it might be of utility to have them connected with the scullery, in such a way as that all sorts of refuse articles might be readily conveyed to them by pipes or other contrivances. When at a distance, they should be so placed as that the servants need not enter the farm-yard in feeding them. It is a circumstance of vast advantage in the economy of labour as well as of food, to have them conveniently situated and built. Though swine are generally, perhaps from a too partial view of their habits, considered as filthy animals, there are no animals which delight more in a clean and comfortable place to lie down in, and none that cleanliness has a better effect upon with respect to their thriving and feeding. In order to keep them dry a sufficient slope must be given, not only to the inside places where they are to lie but to the outside areas, with proper drains to carry off all moisture. The outside should also be a little elevated, and have steps up from the areas of at least five or six inches in height. Hogsties should likewise have several divisions, to keep the different sorts of swine separate nor should a great many ever be allowed to go together for it is found that they feed better in small numbers and of equal size, than when many of unequal sizes are put together. Proper divisions must, therefore, be made some for swine when with the boar others for brood swine, and for them to farrow in for weaning the pig; for keeping the store pigs, for fattening, &c. When convenient, the areas should be pretty large and where it can be had, it is of great use to have water conveyed to them, as it serves many useful purposes.*

5838. *Every sty should have a rubbing-post. "Having occasion," says Marshal, "to shift two hogs out of a sty without one, into another with a post, accidentally put up to support the roof, he had a full opportunity of observing its use. The animals, when they went in, were dirty with broken ragged coats, and with dull heavy countenances. In a few days, they cleared away their coats, cleaned their skins, and became sleek haired; the enjoyments of the post were discernible even in their looks, in their liveliness, and apparent contentment. It is not probable, that any animal should thrive while afflicted with pain or uneasiness. Grasses either angle free to grow or put up dead posts in the ground, for their cattle to rub themselves against yet it is probable that a rubbing-post has never been placed intentionally in a sty; though perhaps, for a two-fold reason, rubbing is most requisite to swine." In farm-yards the piggeries and poultry houses generally occupy the south side of the area, in low buildings, which may be overlooked from the farmer's dwelling-house. They should open behind into the straw yards or dung-heaps, to allow the hogs and fowls to pick up the corn left on the straw or what turnips, clover or other matters are refused by the cattle. They should have openings outwards that the pigs may be let out to range round the farmery at convenient times; and that the poultry may have ingress and egress from that side as well as the other.*

5839. *The pig-house at Harley's dairy establishment (fig. 414) consisted of a number of sties separated from each other by a nine-inch wall each sty consisted of two apartments one for exercise which was open above (a), and the other for feeding in which was covered (b) and a third, also covered, for sleeping in (c). The threshold of the opening to the sleeping apartment was formed by a post-iron trough kept full of water (d), through which the pigs being obliged to pass when they went to sleep, it is said their feet were washed, and their litter kept clean. The water in these troughs was supplied by a pipe at one end, and each separate tank had a waste pipe. The floor of the sleeping place was a few inches higher than that of the feeding apartment, and the floor of the latter and also of the open area were joined towards the middle (e), under which was a sewer with filtering plates for the urine to pass through; and at the end of the sewer a tank (f) received the whole. (Harley's Dairy System, p. 128.)*

2840. *Poultry-houses* are generally slight structures for rearing and feeding domestic fowls. *Easton* (*Conn. to the Board of Agr.* vol. i.) is of opinion, that poultry ought always to be confined, but not in a close, dark, diminutive hovel, as is often the case; they should have a spacious airy place, properly constructed for them. Some people are of opinion, that each sort of poultry should be kept by itself. This, however, is not, he says, absolutely necessary, for all sorts may be kept promiscuously together, provided they have a place sufficiently large to accommodate them conveniently, and proper divisions and nests for each kind to retire to separately, which they will naturally do of themselves. *Wakefield* of *Liverpool* keeps a large stock of turkeys, geese, hens, and ducks, all in the same place and although young turkeys are in general considered so difficult to bring up, he rears great numbers of them in this manner every season, with little or no trouble. For this purpose he has about three quarters, or nearly a whole acre, enclosed with a fence only six or seven feet high, formed of slabs set on end, or any thinnings of fir or other trees split and put close together. They are fastened by a rail near the top and another near the bottom, and are pointed sharp, which he supposes prevents the poultry flying over for they never attempt it, although so low. Within this fence are places slightly constructed (but well secured from wet) for each sort of poultry, also a pond or stream of water running through it. These poultry are fed almost entirely with steamed potatoes, and thrive astonishingly well. The quantity of dung made in this poultry-place is also an object worth attention and when it is cleaned out, a thin paring of the surface is at the same time taken off, which makes a valuable compost for the purpose of manure. But for keeping poultry upon a small scale, it is only necessary to have a small shed or slight building, formed in some warm, sheltered, sunny situation (if near the kitchen or other place where a constant fire is kept so much the better), with proper divisions, boxes, baskets, or other contrivances, for the different sorts of birds, and for their laying and incubation.

2841. *Where a few poultry*, taking their chance at the barn-door are kept by the farmer for the convenience of eggs, and to supply the table when a fowl is wanted, no particular attention is requisite but as, in some situations, they may pay well for more food and closer attention, other circumstances may be noticed. "The poultry-house should," *Young* says, "contain an apartment for the general stock to roost in, another for setting a third for fastening, and a fourth for food. If the scale is large, there should be a fifth, for plucking and keeping feathers. If a woman is kept purposely to attend them, she should have her cottage contiguous, that the smoke of her chimney may play into the roosting and setting rooms, poultry never thriving so well as in warmth and smoke an observation as old as *Columella*, and strongly confirmed by the quantity bred in the smoky cabins of *Ireland*. For setting both turkeys and hens, nests should be made in lockers that have lids with hinges, to confine them if necessary or two or three will," he says, "in sitting crowd into the same nest. All must have access to a gravelled yard, and to green for range, and the building should be near the farm-yard, and have their water near. Great attention should be paid to cleanliness and whitewashing not for appearance, but to destroy vermin."

2842. The exterior arrangement of a poultry-house for a farm-yard is generally very simple, and consists of little more than a number of spars reaching across the building at different heights, or at the same

height, with a gangway or ladder attached, for the fowls to ascend but where comfort and cleanliness are studied, a preferable mode is to form a sloping stage of spars (fig. 415 a b) for the poultry to sit on beneath this stage may be two ranges of boxes for nests (c, d), the roof (e) should have a ceiling to keep the whole warm in winter and the door (f) should be nearly as high as the ceiling for ventilation, and should have a small opening with a shutter at bottom, which where there is no danger from dogs or foxes, may be left open at all times to admit of the poultry going in and out at pleasure, and especially for their early egress during summer. The spars on which the caged birds are to roost should not be round and smooth, but roughish and roughish, like the branch of a tree. The floor must be dry and kept clean for the web-footed kind.

2843. The *rabbitry* is a building of rare occurrence in agriculture, and where it is required differs little from the piggery, consisting of a yard for exercise and receiving food, and a covered close apartment, connected, for repose, sleep, and the mothers and young. In the latter are generally boxes a foot or more high and wide, and divided into compartments of two or more cubic feet for the rabbits to retire into, and bring forth their young. Where young rabbits are fed for the market, the mother and offspring are generally confined to hutches, which are boxes a little larger than the common breeding-boxes, and kept in a separate apartment. In treating of the rabbit (Part III.), these and other contrivances for the culture of this animal will be brought into notice.

2844. The *pigeonry* is a structure not more frequent than the rabbitry, being scarcely admissible in professional agriculture, except in grazing districts, where the birds have not so direct an opportunity of injuring corn. Sometimes they are made an ornamental appendage to a proprietor's farm, or to a sheep-house in a park (fig. 416.), or other detached building; and sometimes a wooden structure, raised from the ground on one post or more, is formed on purpose for their abode. Whatever may

be the external form, the interior arrangement consists of a series of boxes or cavities formed in or against the wall, generally about a foot high and deep, and two feet or less long; one half of the front is left open as an entrance, and the other is closed to protect the female during incubation (See *Pigeon*, Part III.)

416

417

2845 The *agery* is a building or structure seldom wanted, except to protect hives from thieves: then a niche or recess in a wall to be secured in front by two or more iron bars, is a simple and effectual mode. Sometimes apiaries are made ornamental (fig. 417), but the best bee-masters set little value on such structures, and prefer keeping their bees detached in single hives, for sufficient reasons. These hives may be chained to fixed stools in Hush's manner (See *Bee* Part IV.)

#### SECT. II. Buildings as Repositories, and for performing in-door Operations.

2846 Buildings for *dead stock and crop* occupy a considerable portion of the farmery, and include the barn, granary, straw and root-houses, cart-sheds, tool house, harness-room, and, when farming is conducted on a very extensive scale, the smiths and carpenters' work-rooms.

\*2847 The *corn-barn*, or building in which corn is contained, threshed, and cleaned, has undergone considerable change in form and dimensions in modern times. Formerly

418

it was in many cases made so large as to contain at once all the corn grown on a farm; and in most cases it was so ample as to contain a great portion of it. But since the mode of forming small corn stacks became more general and also the introduction of threshing machines, this description of building is made much smaller. The barn, especially where the corn is to be threshed by a machine, is best placed on the north side of the farmery as being most central for the supply of the straw-yards, as well as the stables and cattle-sheds. In this situation it has also the best effect in an architectural and picturesque point of view (fig. 418.) Suppose an octagonal form chosen for a farmery, with the barn (1) straw-room and granary over (2), and mill-shed (3), to the north: then on the left of the barn may be the stable for work-horses (4), and riding-horse stable (5), cattle-house (6), cow house (7) sick horse (8) sick cow (9), cattle-sheds (10), cart-shed (11) boiling and steaming house (12), root-house (13) chaff and other stores for steaming, or mechanics work-shop (14), pigsties (15), poultry-house and rabbitry (16). The yard may be divided in two by a wall running north and south, with a pump, well, or other supply of water in the centre (17). The sick yard (27) should be to the north of such a farmery, for easy conveyance to the barn: the main entrance (28) should be from the south, opposite the dwelling-house side entrances (26) should lead to different parts of the farm and to the main roads of the country, and there should be ponds (25) for washing the horses' feet and for the poultry. The same accommodations may be arranged in a square or circular outline (figs. 418. and 420.)

G g

2848. The *threshing-floor*, in which a large quantity of corn in the straw is to be contained and threshed out with flails, may either be constructed on wooden frames covered with planks of oak, or be built of brick or stone, whichever the country affords in the greatest plenty and in either case there should be such vent-holes or openings in their sides or walls, as to afford free admittance to the air, in order to prevent the mouldiness that would otherwise, from the least dampness, lodge in the grain. The gable-ends are probably best of brick or stone, on account of greater solidity the whole may be roofed with shacks or tiles, as either can be more conveniently procured. It should have two large folding doors facing each other, one in each side of the building, for the convenience of carrying in or out a large load of corn in sheaves and these doors should be of the same breadth with the threshing floor, to afford the more light and air, the former for the thrashers, and the latter for winnowing. Over the threshing-floor, and a little above the rear of the flail poles are often laid across from one beam to another to form a kind of upper-deck upon which the thrasher may throw the straw or chaff, to make an immediate clearing till he has time to stow it properly elsewhere and on the outside, over the great doors, it is sometimes convenient to have a large post-house, made to project sufficiently to cover a load of corn or hay, in case a sudden storm should come on before it can be housed, and also to shelter the poultry in the farm-yard in great heat or bad weather. It was formerly the custom in countries that abounded in corn to have separate barns for wheat for spring-corn, such as barley and oats and for peas, tares, mangel, clover, sainfoin, &c. but where the grain can be stacked, the heavy expense of so many buildings of this kind may be avoided. On no description of farm buildings has so much needless expense been incurred as on barns. The most substantial in England are those on Coke's estate in Norfolk they are built of the white brick, so large and unsuitably constructed that they cannot be filled with corn from the fear of bursting the side walls.

2849. The *threshing-floor*, or space on which the grain is threshed out by the flail, is an important object in the English barn. It is for the most part made in the middle of the building but may be laid down in any other part, if more convenient, and should always be so formed as to be perfectly close, firm, and strong. In constructing these kinds of floors, various sorts of materials are employed, such as compositions of different earthy kinds, stones, lumps, bricks, and wood. The last substance, when properly laid and put together, is probably the best and most secure from damp. When made of wood, they are sometimes so contrived as to be movable at pleasure, which is a great convenience in many cases they are made of different dimensions, but from twelve to fourteen by eighteen or twenty feet are in general proper sizes for most purposes.

2820. *Threshing-floors in Gloucestershire*, Marshal observes, are of a good size, when from 12 to 14 by 12 to 20 feet. The best are of oak, some of stone, but a species of earthen floor, which is made there, is thought to be superior to floors of stone, or any other material, except cement and-planks. The superior excellence of these floors is owing in part to the materials of which they are formed, and in part to the method of making them. In order to this, in some places, the surface of the intended threshing-place is dug away to the depth of about six inches, and the earth thus taken out, when of a proper kind, after being well cleared of stones, is mixed with the strongest clay that can be procured, and with the dung of cattle. This mixture is then worked together with water till it is of the consistence of stiff mortar, and the compost thus made is spread as smooth as possible with a trowel, upon the spot from which the earth was taken. As it cracks in drying it must be frequently beaten down with great force, or rolled with a heavy roller until all the crevices are filled up, and this must be continued till it is quite solid, hard, dry, smooth, and firm.

2821. *Boarded threshing-floors* made of sound, thick, well seasoned planks of oak, are excellent for service, will last a long time, and may be converted into good floorings for rooms, by planing them down, after they are become too uneven for the purpose originally intended.

2822. *Barren threshing-floors* should not be advised, except where good materials can be procured, and the making of them be performed in the most perfect manner which as we have noticed (2820.) is only the case in particular instances and districts.

2823. *Brick floors*, when well laid down, may in some cases, make a tolerable floor for many purposes, but on account of their not only attracting, but retaining, moisture, they are not to be recommended where grain of any kind is to continue much upon them.

2824. *In constructing wooden floors* the most usual mode is that of nailing the planks, or boards of which they are composed, after their edges have been shot true, and well fitted and jointed close down to wooden joists or sleepers, firmly placed and secured upon the ground, or other place for the purpose. But in the midland districts, instead of the planks being nailed down to sleepers in the ordinary way, the floor is first laid with bricks, and the planks spread over them, with no other confinement than that of being "dowied" together that is, ploughed and tongued, and their ends let into sills or walls, placed in the usual way, on each side of the floor. By this method of putting down the planks provided the brick-work is left truly level, vermin cannot have a hiding place beneath them, and a communication of damp air being effectually prevented, floors thus laid are found to wear better than those laid upon sleepers. It is observable that the planks, by this method of laying ought to be thoroughly seasoned. It is evident, however, that where barn floors can be made hollow they must be much better for the purpose of threshing upon, than such as are either placed on brick-work, or the ground. From their greater pliability and elasticity in threshing upon the grain is of course threshed out with more ease, certainty and despatch.

2825. *The threshing-mill barn* is not restricted to any size, but it answers best when the ground-plan is a parallelogram the width from twenty to thirty feet, according to the size of the machinery, and the height from fifteen to twenty feet, in order to allow one winnowing machine, or even two, to be placed under the threshing part of the machinery. The barn in this case is in three distinct divisions the first, for the unthreshed corn should be of such a size as to contain an ordinary stack and, if possible, it should be so contrived as to be entered by a loaded cart which, whether the corn be threshed as carried in, or be laid up for future operations, is a great saving of labour. The second division contains the machinery and the corn floor and should be enclosed with boards so as to be locked up when not in use. The third division is the straw barn, which should be so large as to admit of keeping separately a considerable quantity of different kinds of straw, accessible for fodder and for litter.

\*2826 *The hay-barn* is commonly constructed of timber, and sometimes is open on the south or east, or even on all sides. In Middlesex, there are many hay-barns capable of holding from thirty to fifty and some even one hundred, loads of hay. They are found to be extremely useful and convenient during a catching and unsettled hay-harvest, and also at other seasons of the year. In wet and windy weather, they afford an opportunity of cutting, weighing, and binding hay none of which operations could, at such a time, be performed out of doors. Most farmers agree that hay may be put together earlier, even by a day in a barn, than it would be safe to do in a stack. They advise, however that the sides of the mow should be raked or pulled clear of the quartering of the barn and, when thus managed, they are of opinion that the hay will be as good in the barn as in the stack. In the driest seasons, barns are a saving and, in wet seasons, the ready assistance which they afford, in speedily securing the hay has been known to make a difference in price of twenty shillings per load. Many persons, on the other hand, think hay is more apt to heat in a barn than in the open air and that they present no advantages which may not be obtained by the canvas stack-cover. If they do not possess considerable advantages, then the loss must be great, as the erection of such barns is a heavy expense.

2827 *The granary*, in barns with threshing machines, is sometimes formed immediately above the floor on which the machine works; which, among other advantages, admits of raising the corn to it directly from the ground-floor, either by the threshing-mill itself, or a common windlass easily worked by one man. When it is to be taken out and carried to market, it may be lowered down upon carts, with the utmost facility and despatch. There is evidently no greater expense incurred by this arrangement for the same slope and height of side walls that must be added to the barn, are required in whatever situation the granary may be; and it possesses several advantages. Owing to its being higher than the adjacent buildings, there is a freer circulation of air and less danger of puffing, or of destruction by vermin the corn may be deposited in it as it is dressed, without being exposed to the weather, while the saving of labour in its usual cases considerable.

2858. The construction of the agricultural granary has in it nothing particular; being, in fact, only a well constructed room, where corn is stored, kept more than a month or two, and generally in sacks.

2859. *A detached granary often forms a part of a farmhouse on a small scale*—they should be built with chimneys, and well removed from the entrance of a barn. In order to effect the latter purpose, they should be raised, by means of close pillars, about eighteen inches or two feet, and have a frame of some durable wood, with quartering of chains, so placed as that they may be filled up closely with bricks, and the inside made secure by being lined with thin boards nailed firmly to the different pieces of quartering. The doors must be made firm, close, and even—the outside may also be covered with boarding, if it be thought necessary and the roof well tiled. There may be different floors or stories, according to the room required.

2860. *Of commercial corn granaries, some of the most extensive are in Danial.* They are seven, eight, or nine stories high, having a funnel in the midst of every floor, to let down the corn from one to another. They are built so securely, that, though every way surrounded with water, the corn contracts no damp, and the vessels have the convenience of coming up to the walls for their lading. The Russians in the interior of the empire preserve their corn in subterranean granaries, of the figure of a sugar-loaf, wide below and narrow at top, the sides are well plastered, and the top covered with stones. They are very careful to have the corn well dried before it is laid into these store-houses, and often dry it by means of ovens, their autumn being too short to effect it sufficiently.

2861. *A granary to preserve corn for many years* should be a dry cellar, deeply covered with earth; and after the corn is put in, hermetically sealed to exclude heat, air and moisture, and provide the possibility of the grain vegetating, or of the existence of insects or vermin, or the hatching of their eggs. (See 1854.)

2862. The root-house is used for storing up or depositing potatoes, turneps, carrots, cabbages, or other roots or tops for the winter feed of cattle. It should always join the cattle-sheds, and communicate with them by an inner door that opens into the feeder's walk by the heads of the cattle. The entrance door ought to be so large as to admit a loaded cart. These houses are essentially necessary wherever there are a number of cows, or other sorts of cattle, to be supported on roots of the carrot, parsnep, turnip, and potato kinds, as well as for cabbages—as without them it would not only be inconvenient, but in many cases in severe weather impossible, to provide them for the daily supply of such stock. Cabbages should not, however, be kept long in houses, as they are very apt to take on the putrid fermentation, and become useless. The master should be careful that the yard man constantly keeps such places perfectly clean and sweet, in order that the roots may contract no bad smell, as cattle are in many cases extremely nice in their feeding, and when once disgusted with any sort of food, seldom take to it again in a proper manner.

2863. The steaming-house should be placed next the root-houses, for obvious reasons, and have an inner floor communicating with it in a line with the door of the feeder's walk.

2864. The straw-house or straw-shed, when there is one distinct from the barn, should be placed at the end of the cattle-sheds, opposite to the root-house, and like it should have a cart entrance, and an inner door communicating with the feeder's walk. Straw however is often stacked, in preference to placing it in a straw-house, especially when large quantities of corn are threshed at one time.

2865. Cart-sheds, or lodges for the shelter and protection of carts or waggons, and other large implements, are generally built close on three sides, with the fourth open, and the roof supported with posts or pillars. Sometimes they are open on all sides (fig 421), but this admits too much wind, which carries moisture with it in the cold seasons of the year and dries up and shrinks wooden articles in summer. Their situation in the square should be apart from the buildings for live stock, and also from the barn, straw, and root houses—generally the first part of the east or west side on entering is devoted to the purpose of cart-sheds and tool-houses.

2866. The tool-house is used for keeping the smaller implements used in manual labour in the fields, as spades, rakes, forks, &c. It is essential that this apartment be dry and free from damp, and, when convenient, it should have a loft for the better preservation of sacks, cordage, sowing seeds, baskets, spare harness, &c.

2867. Some other buildings, besides those of this and the preceding section, will be wanted in most farm-yards of any extent, as stables for young horses, riding-horses, an hospital stable, &c. Particular descriptions of farms also require appropriate buildings, as dairies, cheese-rooms, hop-presses, and wood-lofts, which will be considered in treating of dairy farms, hop culture, the management of sheep, &c.

2868. Sleeping-rooms for single men should be made over the stable, and for the feeder or cow-keeper over the cattle-sheds, that they may hear any accident which takes place among the horses or cattle during the night, and be at hand to remedy it.

2869. A smithy, and carpenter's work-rooms, sometimes form part of the buildings on a large farm. Instead of going to a distance to the residence of these necessary mechanics, arrangements are made with them to attend at stated periods, or when sent for, by which a saving both of time and money is effected. Sometimes these buildings are set down at a little distance from the square, to prevent danger from fire, and lessen the expense of

421

insurance. The fixtures, as the anvil, bellows, bench, vice, lathe, &c. and some of the larger tools, belong to the farmer, but the others the mechanics bring with them. A small stock of iron, steel, and timber is kept, to be in readiness and also the cast-iron work of ploughs, carts, &c., and sometimes the smaller pistons, and other parts of the threshing machines.

SECT. III. *The Farmer's Dwelling-house.*

2870 *The dwelling-house of the farmer is generally detached from the farmery on the south side, and separated from it by a road, grass-plot, garden, or pond, or all of these, according to circumstances. In size and accommodations it ought to be proportioned to the capital requisite for the farm; that is, it ought to be on a par with the houses of other members of society of similar property and income. In design it ought to be simple and unostentatious, utility and convenience being its recommendatory beauties. At the same time, as observed in the Code of Agriculture, "every landlord of taste, in fixing on the site and plan of a new farm-house and offices, ought certainly not to overlook the embellishment of the country." How much of the beauty of a country and of the ideas of the comfort and happiness of its inhabitants, depends on the appearance of its farm-houses and cottages, every traveller is aware and every agriculturist who has travelled through the British Isles can recognise at once a well cultivated district by the forms of the farm-yards, and the position of the farmer's dwelling-house. The difference between the best and worst cultivated English counties in this respect is sufficiently striking and the ideas of wealth, comfort, order and scientific agriculture, which the farmhouses and cottages of Northumberland and Berwickshire excite in the mind, are totally unfit in passing through even Hertfordshire and Essex; where the scattered straggling hovels of all sizes and shapes, the monstrous barns, and rickety shapeless farm-houses, indicate a low state of culture, and an ignorant tasteless set of occupiers. Even in Norfolk and Suffolk the want of symmetry in the farmhouses of opulent farmers is every where conspicuous and the want of taste and decorum in setting the dwelling-houses among dung heaps and urine ponds no less so.*

2871 *In selecting a few examples of farm-houses, the first we shall notice is that of the smallest size, where the farmer keeps no servant and cultivates only a few acres. The ground plan of such a house (fig. 422) should contain an entry (a) kitchen (b) dairy and pantry (c), parlour (d), light closet off the parlour as a store-room, or for a bed (e) tool-house (f) stair and cellar under (g) water-closet, and poultry-house over (h) there are three bed-rooms in the roof and one garret. The dimensions may be varied at pleasure, but twelve feet square is the least dimension that can be given to the kitchen and parlour.*

2872. *A farm-house of the smallest size (fig. 423), where the poultry and tool houses are in the farm-yard, but where the farmer keeps only one servant, and works and lives with him, may contain an entrance and stair (a), kitchen, closet, and oven B; back kitchen (c); dairy (d), parlour (e) bedroom (f), with three bed-rooms and a G g s*

garret up-stairs, and a cellar under. The arrangement of this ground plan is excellent, with the single exception of the situation of the fireplace, which in no cottage or small dwelling-house ought to be in the outside wall. A few of such farm-houses and tenants should be found in all parts of the country if for no other reason than to preserve the gradation from the labourer to the professional farmer, and from the cottage to the farm-house.

2873. *A farm-house larger than the preceding (fig. 424), and for a farmer and his family rather in a better style, may contain a principal entrance and lobby (a); parlour (b), closets (c); store-room for meal, cheese, &c. (d), lumber room for small implements (e) beer cellar (f); pantry (g) dairy (h), staircase (i), kitchen with an oven under the stairs, and a boiler on the other side of the fireplace (k) coals or wood, and back entry (l); pigsty with a small opening towards the kitchen for throwing in dish-water, offal, &c. (m) and poultry-house (n); with two garret bedrooms over the wings, two good bedrooms and a closet up stairs, and a garret in the roof.*

2874. *A farm-house of the second lower scale (fig. 425), executed at Burleigh in Rutlandshire, contains a principal entry (a) parlour (b) kitchen (c), stair (d), dairy (e) pantry (f) cellar (g) and cheese-room (h). The three latter are attached to the back part of the house by a continuation downwards of the same roof. By making their ceilings only seven and a half or eight feet high, some small bedrooms may be got above them, having a few steps down from the floor of the front rooms, or a few steps up from the first landing-place. The back door of the kitchen enters into a brewhouse and washhouse, the fireplace and copper being behind the kitchen vent. Beyond this brewhouse is a place for holding fire-wood, &c., in the back wall of which are openings to feed the swine. In the kitchen is an oven and below the grate a very good contrivance for baking occasionally but principally used for keeping the servants' meat warm; it consists of a cast-iron plate, and door like an oven. The chamber-floor is divided into two rooms forwards, and two small ones backwards.*

2875. *Farmer's dwelling-houses, containing more accommodation and comfort, and displaying appropriate taste and expression of design, will be found in a succeeding section, where farmsteads are treated of, and also where we treat of laying out farms. (Part III.)*

#### SECT. IV Cottages for Farm Servants

2876. *Cottages for labourers are necessary appendages to every farm or landed estate, and no improvement is found to answer the purpose better than building these on a comfortable and commodious plan. In the southern counties of the island, where the farmer's labourer is supposed to change his master once a year, or oftener, the whole business of cottages is commonly left to accident; but in the north a certain number of married servants are kept on every farm, and a fixed place near the farmstead is appointed*

for their situation. These habitations are in the tenure of the farmer, is common with the other buildings of the farm, and whenever a married servant changes his master he changes his habitation.

3577. The accommodation formerly considered suitable for farm labourers consisted of two rooms. That on the ground floor not being less than twelve feet square, with a sleeping-room of the same size over, and sometimes on the same floor. But this is justly deemed too small for an ordinary labourer's family. "Humanity," Eastern observes, "shudders at the idea of an industrious labourer with a wife and perhaps five or six children, being obliged to live, or rather exist, in a wretched, damp, gloomy room, of ten or twelve feet square, and that room without a floor; but common decency must revolt at considering that over this wretched apartment there is only one chamber to hold all the miserable beds of this miserable family. And yet instances of this kind, to our shame be it spoken, occur in every country village. How can we expect our labourers or their families to be healthy or that their daughters, from whom we are to take our future female domestics, should be cleanly modest, or even decent, in such wretched habitations?"

3578. The accommodation which the smallest cottage ought to have, according to Waitstill, is a kitchen, washhouse, and closet, or pantry with two bed-rooms. A parlour is almost useless. The kitchen, being freed from the business of washing and baking, may always be kept decent for the family to live in; and a decent kitchen is greatly preferable to a disorderly parlour, and a parlour that is not used often or perhaps, than two or three times a year, will seldom be kept in order. Every cottager who has a family of children at home, ought, for decency's sake, to have two bedrooms and if the children are of both sexes he ought to have three. For the purpose of thoroughly airing and sweetening the bedrooms there ought to be windows to all the rooms. (Waitstill's Designs, &c. p. 81.) If the rooms of a cottage be built too low or in any other respect upon a bad plan, the inconveniences arising from these circumstances will in all probability have to be endured by its successive occupants as long as the materials of which it is composed will last. If therefore, the welfare of the inhabitants of such dwellings be considered, it is highly important that any circumstances which would thus entail the want of comfort should be avoided, and it must be gratifying to those who erect durable and efficient cottages, in healthy situations, with gardens attached, to contemplate on what industry, what cleanliness, what happiness, and, in short, what great and lasting improvement in the condition and habits of this class of their fellow-beings, they may, as they have it in their power by a little attention, so really and so beneficially to themselves as well. (Id. p. 14.)

3579. Cottages for farm servants. It is observed by the able author of the article *Agriculture*, in the *Supplement to the Encyclopædia Britannica* are usually set down in a line at not an inconvenient distance from the farm-yard. Each of them contains two apartments with fireplaces, and garret sleeping-rooms over. Adjoining is commonly a cow house, hogsty shed for fuel, necessary a small garden, and sometimes other appendages of comfort and enjoyment. As an example of the minimum of modern accommodation, we may refer to two cottages on a farm in Berwickshire, as described in the report of that county. They contain each a kitchen (A) 485. a, small parlour and store-room (b) with two good bedrooms over and a dairy under the staircase. — There is a garden behind (c), a place for a calf or pig, or for fuel (d), water-closet (e) and dung-heap (f). The labourer's cows, in this case, are kept at the farm along with those of the farmer.

It is proper to observe, however that this is more the house of a farm servant in Scotland than the reality. With the exception of some cottages that have been recently built by Englishmen who have become possessed of property in Scotland, such as the Marquess of Stafford, Earl Grey, &c. the dwellings of the labouring classes are a disgrace to the country. It is any thing but creditable, both to the landed proprietors and the farmers, that while the houses of both have been greatly improved in comfort and appearance within the last thirty years scarcely any improvement has taken place in the dwellings of their servants. Even in East Lothian, Berwickshire, and other counties, generally considered the most improved in Scotland, scarcely any alteration has taken place for the better within our remembrance. One cause, no doubt, of this want of comfort and the appearance of enjoyment in Scottish cottages, is owing to the ignorance of the cottages of many of the comforts which are enjoyed by the same class in other countries, and more particularly in England, Holland and the South of Germany. This applies particularly to tradesmen cottagers, or what may be called independent occupiers; but with respect to all those cottagers who are the hired servants of owners or occupiers of land, the blame belongs wholly to the owners and occupiers, and may be traced to their want of sympathy for their fellow-men, as well as a want of an enlightened view of their own interests. "Could the rich," Waitstill remarks, "but consider themselves interested in the appearance of their tenants and labourers, and hold the improvement of the cottage and cottage garden, and its inhabitants, as an essential part of the improvement of their grounds; they would thus make their seats agreeable to the growth of plenty diffused, and not the solitary instance of wretchedness in the midst of wretchedness, at once to its neighbour and its reproach."

(Waitstill's Designs, &c. p. 8.)

3580. A double plan of a cottage and cow-house (A) 487 may be thus arranged. Both may contain a kitchen (a) with an oven, and there may be a small parlour or store-room (b), a dairy and pantry (c), with two bedrooms over. Detached may be a dairy (d), water-closet (e), place for fuel (f), and cow-house (g), with garden adjoining, dung-heap, porch, sheep-pen, &c. as in the plan plan.

G g 4

2884. In regard to the construction of cottages much information may be obtained from a work entitled *A Series of Plans for Cottages*, by J Wood of Bath. This author lays down the following seven principles as the means of obtaining the inconveniences to which cottages, as usually built, are liable.

2885. *The cottage should be dry and healthy.* This is effected by having the floor six feet or eight inches above the natural ground, by building a clear of banks, or a open spot of ground, that has a declivity or fall from the building, by having the rooms not less than eight feet high,—a height that will keep them dry and healthy; and by avoiding having chimneys in the roof.

2886. *They should be warm, cheerful, and comfortable.* In order to obtain these points, the walls should be of a sufficient thickness (if of stone, not less than sixteen inches; if of brick, at least a brick and a half) to keep out the cold of the winter, or the excessive heat of the summer. The entrance should be screened, that the room, on opening the door, may not be exposed to the open air. The rooms should receive their light from the east, or the south, or from any point between the east and the south; for, if they receive their light from the north, they will be cold and cheerless; if from the west, they will be so heated by the summer's afternoon sun, as to become contraries to the poor labourer, after a hard day's work; whereas, on the contrary receiving the light from the east or the south, they will be always warm and cheerful. So his the feelings of men in a higher sphere are those of the poor cottager, that if his habitation be warm, cheerful, and comfortable, he will return to it with gladness, and abide in it with pleasure.

2887. *They should be rendered convenient,* by having a porch or shed, to screen the entrance, and to hold the labourer's tools; by having a shed to serve as a pantry and store-place for fuel; by having a privy for cleanliness and decency's sake; by a proper disposition of the windows, doors, and chimneys; by having the stairs, where there is an upper floor, not less than three feet wide, the rise or height not more than eight inches, and the tread or breadth not less than nine inches; and, lastly, by proportioning the size of the cottage to the family that is to inhabit it; there should be one lodging-room for the parents, another for the female, and a third for the male children. It is melancholy he says, to see a man and his wife, and sometimes half a dozen children, crowded together in the same room, nay often in the same bed, or in case of illness, or of death; indeed, whilst the children are young, under some years of age, there is not that offence to decency if they sleep in the same room with their parents, or if the boys and girls sleep together, but after that age they should be kept apart.

2888. *Cottages should not be more than twelve feet wide in the clear,* that being the greatest width that it would be prudent to venture the rafters of the roof, with the collar pieces only, without danger of spreading the walls; and, by using gullies, there can be fifteen inches in height of the roof thrown into the upper chamber, which will render domestic windows useless.

2889. *Cottages should be always built in pairs* either at a little distance from one another, or close adjoining, so as to appear one building, that the inhabitants may be of assistance to each other in case of sickness, or any other accident.

2890. *For economy cottages should be built strong,* and with the best of materials, and these materials well put together. The mortar must be well tempered and mixed, and lime not spared; hollow walls being on decay and harbour vermin; and bad every timber soon reduces the cottage to a ruinous state. Although cottages need not be fine, yet they should be regular, regularly will render their ornaments to the country instead of their being, as at present, disagreeable objects.

2891. *A piece of ground should be allotted to every cottage* proportionable to its use, the cottage should be built in the vicinity of a spring of water—a circumstance to be attended to and if there be no spring, let there be a well.

2892. On the foregoing seven principles he recommends all cottages to be built. They may be divided into four classes or degrees: first, cottages with one room; secondly, cottages with two rooms; thirdly, cottages with three rooms; and, fourthly, cottages with four rooms. Plans of each of which, having great merit in their distribution, may be seen in his very able work.

2893. *An economical mode of constructing the walls of brick-built cottages* is described by Deane, in a *Treat on Hollow Walls* (London, 1821). These walls are only nine inches wide, and built hollow, by laying the courses alternately lengthwise on edge, and crosswise on the broad face. Another description of hollow walls has been invented by Silverlock of Chichester, and used by him in building garden walls (See *Encyc. of Gardening*) in which all the bricks are laid on edge, but alternately along and across the wall or in bricklayers language, header and stretcher. Either of these modes suits very well for cottages of one story, and if well plastered inside the house, they will be warmer and drier than solid walls even of fourteen inches thickness. Hollow walls of any height may be built by laying the bricks flatwise, and joining the outer and inner four-inch, or single brick, walls, by cross bricks at moderate distances.

2894. *Mud walls*, built in the French manner, or *en pisé*, are recommended by Beaton, Crocker, and others, and also "walls composed of soft mire and straw" but these last we consider, with Wood, as the reverse of economical in the end, and totally unfit for our climate and degree of civilization.

2895. *An economical mode of forming staircases to cottages*, is described by Beaton, and has been adopted in a few places. Its merit consists in occupying exactly half the room which is required for stairs on the ordinary plan. This is effected by dividing every step into two parts (fig 481 a and b), and making one part double the height of another. In ascending such a stair the left foot is set on the left step (a), and the right foot on the right step (b) alternately to the top of the stair. It is therefore clear, that as the steps for the right and for the left foot are in the same line, and although neither foot rises each time higher than seven inches and a half above the other, yet every time that one foot is moved, it rises fifteen inches higher than it was before. Suppose in a stair of this kind, that each tread or breadth for the first is nine inches, and that each rise of the one foot above the other is seven inches.

and a half simultaneously, as each foot rises the height of two steps, or fifteen inches, every time it is moved, it is plain that six steps of this kind will rise as high as twelve in the common way, and will require only one half the size of a hatch or opening in the floor above, that would be required for those twelve steps as usually constructed. This will be of considerable advantage, where much is required to be made of little rooms, and will of course give more space to the chambers above; but it has the disadvantage of being disagreeable, and even dangerous to descend, especially for pregnant women and young children.

2896. Of what are called *ornamental cottages for labourers*, we shall say little. Utility is a beauty of itself, but there are higher degrees of that sentiment excited by the appearance of convenience and abundance by the evidence of design or intelligence in the contriver as displayed in the elevation and general effect, and by classical, imitative, or picturesque forms in the masses and details. The great evil, however, is, that these ornamental cottages, as generally constructed, are felt by the occupiers to be very uncomfortable habitations, every thing being sacrificed by the designer to external appearance. This is in the very worst taste, and has, in most parts of the country, brought ornamental cottages into ridicule. Utility, therefore, is the main consideration, and nothing ought to

be considered as ornamental that is at all at variance with this property.

2896. A cottage ornamental in the second degree (Fig. 438) contains an entrance and lobby (a), kitchen (b), stair (c), parlour or store-room (d), back kitchen (e), cowhouse (f) and water-closet (g), with two good bedrooms over the centre of the building, and two garrets over the wings.

2897. As an example of a cottage ornamental in the least degree (Fig. 439) we submit a specimen in the gothic style, by Holland. It contains an entrance lobby and stair (a), kitchen (b), small parlour and store-room (c), cowhouse (d), pigsty (e), poultry house (f), and water-closet (g). Over the kitchen is a bedroom with a fireplace, and another communicating with it over the cowhouse.

2898. A double ornamental cottage, erected by Lord Penrhyn, in Wales (Fig. 439), contains a porch, lobby, and stair (a), kitchen and living room (b), parlour (c), with cellars and pantry under and to each house, two bedrooms over. It must be confessed, however, that this cottage is more ornamental than convenient.

2899. A double ornamental cottage with lat. woodwork (Fig. 435), built in Hertfordshire, on a very dry soil, contains, on the ground floor, the kitchen and living room (a), pantry (b) and small light closets (c), with a stair up to two good bedrooms

above, and down to a dairy cellar, fuel-room, and other conveniences beneath. It is placed in a most garden, with pigsty, bee-hive, poultry dung-heap, water-closet, covered cart or horse pump-well, and other appendages to such cottages.

2901. A variety of other plans of cottages will be found connected with the plans of farmhouses, and in our *Topography of Agriculture* (Part IV.)

**Plan. V** *Stack-yard, Dung-yard, and other Enclosures immediately attached to Farm Buildings.*

2902. *The different appendages which are common to farm buildings are the dung-yard, pits and reservoirs, the rick-yard, the straw yard, the poultry-yard, drying-yard, garden, orchard, and cottage-yards. These necessarily vary much, according to situation and other circumstances, but all of them are more or less essential to a complete farmery.*

2903. *The dung-yard and pit is placed in almost every case in the centre of the main yard. A pavement, or causeway, ought to be carried round the yard, next to the houses, of nine or fifteen feet in width, according to the scale of the whole: the remaining part of the yard should either be enclosed with a wall with various doors to admit cattle, carts, and wheel-barrows, or, on a small scale, it may be entirely open. From this space the earth should be excavated so as to form a hollow deepest at the centre, or at the lower end if the original surface was not level and from the lowest part of this hollow should be conducted a drain to a reservoir for liquid manure. The bottom of this excavation, or dung-bann, ought to be rendered hard, to resist the impression of cart wheels in removing the dung, and impervious to moisture, to prevent absorption.*

2904. *For these purposes, it may be either paved the stones being set on a layer of clay; or what will generally answer equally well, it may be covered with a thick coat of gravel or chalk, if it can be got, and then well rolled, mixing some loam with the gravel if it is found not to consolidate readily. To prevent, as much as possible, a superfluity of rain-water from mixing with the dung and disturbing its drainings all external surface-water should be prevented from entering the farm-yard by means of drains, open or covered and that which collects on the inner slopes of the road, should, in every case, be carried off by gutters. Such is the opinion of most agriculturists as to the situation of the farm-yard, dung-bill, and reservoir; but, in addition to these requisites, it is now very properly considered as equally important that there be urine-pits, either open or covered.*

2905. *The urinarium, or urine-pit is constructed in or near to the stables and cattle-sheds, for the immediate reception of the drainage of these buildings unmixed with rain-water. It is found from experience that a very considerable addition of the richest kind of manure is thus obtained on every arable farm. At the same time it is proper to observe, that no benefit, but a loss, will arise, if the urine is so completely drained from the straw as to leave it too dry for fermentation. Where there are no stall-fed cattle an able author (*Supp. Enc. Brit.* 1. 181) is of opinion there will be no more urine than what will be required for converting the straw into manure. Where cattle are fed at the stake, however he considers a reservoir as essential. Allan, of Craigcrook near Edinburgh, recommends that there should be two, in order that as soon as one is full, it should remain in that state till the urine becomes putrid before it is taken away. The urine is either applied to the land in its liquid state, or mixed with peat, earth, &c. The reservoirs may be either vaults of masonry or wells in either case, the hole for the pump should be sufficiently large to admit a man to clean out the sediment when it accumulates. A very desirable plan seems to be, to have these vaults, or wells, chiefly within the cattle-house, as in Flanders, but partly also without, to admit room for the pump-hole, close by the wall on the inside of the surrounding paved road. It is need less to add, that such constructions ought to be made water-tight by the use of some cement, or by puddling with clay outside of the masonry.*

2906. *The stack-yard, or enclosure within which corn, hay, &c. are stacked, is placed exterior to that side of the building which contains the barn. Stack-yards should always be sufficiently spacious and airy, having a firm dry bottom and some advise them to be ridged up, to prevent the accumulation of surface-water as by raising the ridges pretty well in the middle, and covering the places where the stacks are to be built, either with rough stones, with a mixture of gravel, or with pavement in the same manner as streets, much advantage would be gained at little expense: but a much better method is to have them raised considerably above the surface, and placed upon pillars of wood or stone, with a covering of wood round the circumference, and beams laid across. The enclosing of stack-yards should be well performed, either by means of walls or palings, or better with a sunk fence, as in this way the stacks will have the full benefit of the air from top to bottom, — a circumstance of no small moment, since it is often found, especially in wet seasons, where the fence of the stack-yards is only a low wall, that the whole of the stacks are damaged or spoiled as high up as the wall reaches, while the upper part is perfectly safe. Should any addition be required to the sunk fence, a railing upon the top may be quite sufficient. This fully shows the vast advantage of having stack-yards sufficiently airy. The proper arrangement of the stands, for their being removed to the threshing-mill, is also a matter of much consequence, in the economy of the work that is to be performed in them.*

2907. *A stack-yard, arranged on principles peculiarly well planned and judicious, has been formed by Mitchell, of Balguburn near Alloo. His stacks are divided into regular rows, and there is a road on each side of every double row besides a road round the whole yard. This plan is attended with the following advantages: 1st, by these parallel roads, there is a greater degree of ventilation; 2dly, he can remove any stack he pleases, as seasonally or markets may require; 3dly in the hurry of harvest there is no detriment or loss of time, whatever may be the number of men or horses employed; and 4thly, by having the rows and the stacks regularly numbered, there is no difficulty in ascertaining what each field of the farm produces.*

2906. *Corn-stands* are requisite fixtures of the stack-yard; they are basements of timber or stonework, or sometimes of iron, on which to build the stack, and their object is to keep the lower part of the stack dry, and exclude vermin. The usual mode of constructing stands is to place a stout frame of timber on upright stones, two feet high, and having projecting caps of flat stones. They are also constructed wholly of stone, with circular or polygonal walls (fig. 436 a, b), built to the same height as in the former case, in a rather sloating manner outwards, and covered on the tops with copings of oak-planking or flat stones, which project over the edges several inches, and in that way prevent the ascent of rats and mice to the stacks. In both these modes, pieces of timber are placed as a frame in the middle to support the grain upon, and generally a cone of spars in the centre, to form a column of air in the heart of the corn. Some suppose the first of these sorts of corn-stands to be the best for general purposes, as being more easily as well as more cheaply constructed, and at the same time permitting the air to enter and circulate with more freedom underneath, in the bottom of the stand, which is of much advantage. It is obvious that the form of these stands or basements must vary according to that in which the stacks are to be made, which is different in different districts. But wherever the threshing machine is introduced, the circular base, as producing a stack of a moderate size, with other advantages, is generally preferred. But cast-iron stands (fig. 437) with or without funnels, are now found preferable in point of economy, and admit of stacking the corn somewhat earlier. The pillars of these stands are three feet high, and weigh half a cwt. each. A stack requires seven pillars, besides the framing, which may either be made of poles or young trees. In the wet climate of Clackmannanshire, wheat has been stacked in five days, beans in eight, and barley and oats in ten days, and sometimes earlier. No vermin can find their way into these stacks in consequence the grain, and the straw is better preserved. The cone or triangle keeps up a circulation of air, and prevents heating or other damage (*Gen. Rep. of Scotland*, vol. iv App. p. 378.)

2908. *Walden's circular rick stand* (fig. 438) is twelve feet eight inches in diameter. It consists of two concentric circular walls, the outer twenty and the inner eighteen inches thick, the outer wall covered with flagstones, which project four inches over it, to prevent rats and mice from getting up into the rick. The space between the two walls is twenty inches wide across this space are laid hedgestakes, which are sufficiently long to support the rick, so that no large bearers are wanted, nor other strong and expensive bearers of any kind. The outer wall is twenty inches high to the top of the projecting flags at about half its height, four grates of cast iron, about six inches square and half an inch thick, are placed in openings left through the external walls, at equal distances from each other to admit air. The bars of the grates are a quarter of an inch broad, and a quarter of an inch distant from each other which is sufficiently close to prevent the entrance of mice. Stands thus constructed are considered, by those who have tried them, to be less expensive and more effective than on any other plan that has been yet invented. The air that passes through these four grates, and through the openings in the internal walls, will circulate freely under the rick and if a chimney be carried up the middle of the rick to its top, the current of air that will pass up through it will carry off the heat and moisture, which might otherwise injure, and even spoil, such corn as was rather too moist when carried. (*Walden's Designs*, &c. p. 101.)

2910 *Hay-stands*, according to some, may be formed in the same manner as those for corn, only it is seldom necessary to have them made of such expensive materials.

A simple frame of wood is mostly sufficient, with proper bearers laid across for the support of the stack, and these stands are much better than loose pieces of wood laid across at the bottom, and filled in with brush or faggot wood, on which ricks are commonly built. Earthy floors or foundations should never be thought of for this purpose, as the dampness must injure a considerable part of the hay at the bottom; but where faggots are not scarce, and the ground on which the hay-stack is built is rather elevated, no stand can ever become necessary.

2911. The *stack-funnel* frames or bees (fig. 439 a.) as it is called in the north, whether the stand be of wood, iron, or stone, may be formed of a few poles placed on a

circular, square, or angular beam, having a few short spars nailed across, or a straw rope wrapped round.

9912 *The stack-cover* is a cloth or canvas covering, for ensheathing over stacks during the time of their being built to protect them from rain. A simple implement of this sort has long been in use in Kent; but it has been improved on by Sir Joseph Banks, so as to become more manageable, though somewhat more costly. It consists of two long upright poles fixed into two cart wheels, a rope, managed by blocks and tackle, connects the poles at top, and supports, raises, or lowers the canvass roof in the usual manner of managing tents and sails. Its construction and use will be afterwards more particularly described.

9913 *The straw-yard* is a term applied to enclosures in or about the farmyard, in which cattle are turned in loose to eat straw. In most cases this enclosure occupies the centre but in some cases enclosures and sheds are erected exterior to the farmyard, and near the straw and root house. The great object in arranging straw yards of this description, is to provide a sufficient extent of sheds open to the south for cover to the cattle in severe weather, and high fences or sheds on the east or west sides, according to their position with relation to the main yard, for shelter.

9914 *The poultry-yard* in most cases may be a very small enclosure as the poultry of common farmeries should be allowed to range over the straw yards and most parts of the premises, to pick up what cannot be got at by swine.

9915 *A tradesman's yard* or small enclosure is often appended to the smith's and carpenter's shops, as well to contain timber as implements in want of repair, &c.

9916 *A kitchen-garden* is an essential appendage to the dwelling-house. Its situation should be apart from the farmery so as not to interfere with it, or be injured by the blowing in of straws, &c. The size of the garden will of course, depend somewhat on that of the house and farm, but as a small farmer with a large family will require as many or more vegetables than one of a higher class, there can be no impropriety in the garden being large. As potatoes and turnips, and sometimes other vegetables, may be had of better quality from the field, some abatement of size may be allowed on this account. In general, the garden need not be under a fourth of an acre, nor exceed twice that quantity. The best fence is a wall, and next a close oak paling but if neither of these can be had, a thorn hedge will answer, though it harbours vermin, and its roots always rob a portion of the accompanying border. The best form is a parallelogram, lying east and west, which may be intersected by walks, so as to divide it into four or six other parallelograms, with a surrounding border as broad as the enclosure fence is high.

9917 *An orchard* may either be regularly formed on an allotted space; or fruit trees may be scattered over a lawn or piece of grass ground which may surround the house. In a convenient part of this orchard, posts should be fixed to form a drying ground, unless the drying is performed by heated air or steam in the house.

9918 *The garden appended to the labourers' cottages* may contain from one eighth to one sixth of an acre. Their situation should always adjoin the house; but whether they should surround it or enclose it on one or more of its sides, must depend on the position of the cowhouses belonging to each cottage. In some cases, and perhaps it is the best plan, these cowhouses form a range by themselves, in a small field devoted to their use, and situate behind the row of cottages.

#### SECT. VI. *Union of the different Farm Buildings and Enclosures in a Farmery.*

9919 *In fixing the arrangement of a set of farm buildings*, the first things, according to Beaman, to be taken into consideration, after choosing the situation, are the nature and produce of the farm. From these may be judged the different kinds of accommodation that will be necessary. For example, every farm must have, first, a dwelling-house, secondly a barn suitable to the extent of arable land in the farm, either with or without a threshing-mill, but always with one, if possible, and so placed as to go by water, if a supply can be had, thirdly stables, the dimensions of which must be determined according to the number of horses necessary for the farm, fourthly, cowhouses, or

feeding-house, or both, according to the number of cows and cattle and so on, till the whole accommodation, and their dimensions, are fixed upon. Having ascertained these, and the situation for building on being also settled, the ground must be carefully and attentively viewed, and if not very even, the different levels must be observed, and the best way of conducting all the necessary drains, and carrying off all superfluous moisture; and also the best situations for dung and urine-pits, or reservoirs, which will, in a great degree, ascertain at once where the cattle-houses and stables should be. These being fixed on, the barn should be as near them as possible, for the convenience of carrying straw to the cattle, and the barn-yard should be contiguous to the barn. These main points being determined on, the others will easily be found always observing this rule, to consider what is the nature of the work to be done about each office, and then the easiest and least laborious way to perform that work, so far as it is connected with other offices. In case this should not be sufficiently explicit, suppose, by way of illustration, the situation of a feeding-house is to be considered of. The nature of the work to be performed here is, bringing food and litter to the cattle, and taking away their dung. The place from which the greatest part perhaps of their food and all their litter comes, is the barn; therefore the feeding-house should be as near the barn as possible. If turnips or other roots, or cabbages, make a part of their food, the most commodious way of giving these must be determined on whether by having a root-house adjoining the cattle-house, and that filled occasionally or by having a place to lay them down in, near the head of the stall from which they are thrown in at holes left in the walls for that purpose. The easiest method of clearing away the dung must also be considered, and the distance from the main dung-pit and urine reservoir. The same general rule being observed in determining on the site of all the other offices or accommodations, together with a careful examination of the ground to be occupied (upon which the arrangement of the offices in a great measure should depend) any person conversant in rural affairs, who attends to these particulars, and can lay down his ideas in a drawing, may easily direct the planning and building of a very commodious set of offices. With respect to the site of the dwelling-house, it may be remarked, that, although the middle of a regular front is in some points of view the most pleasing, and in many situations perhaps the best, yet, unless the ground and other circumstances in every respect favour such a disposition, it should not invariably be adhered to for it may often happen that a much better situation for the dwelling-house may be obtained at a little distance from the offices, a pleasing uniformity be observed in them at the same time, and the house be more healthy and agreeable. In some cases, and for some kinds of farms, it may be particularly necessary to have the house so placed, in respect to the offices and farm yard, as to admit of their being constantly inspected, and the labour that is to be performed in them attended to and overlooked.

2920. *Farm buildings in the colder latitudes of Europe and America* are most advantageously condensed together under one roof and on a square or parallelogram ground plan. The saving in the first erection, and in all future repairs, is very considerable and not less so the saving of heat during the severe weather of winter. In such countries open straw-yards for cattle are not wanted; for in summer these are either in the fields, or stall-fed, and in winter both cattle and sheep are kept almost always in the house. In Britain, however, where the winters are mild, and where it is the custom to keep cattle loose in the straw yards, it is found desirable to distribute the buildings around such yards, for the sake of shelter to the cattle but in the case of sheep farms, or where all the cattle kept are stall-fed, there seems no reason why the greater part of the buildings of a farmery might not be included in a cube with a single roof.

2921. *Wicksell* considers a "parallelogram the most ample and least expensive form for the arrangement of farm buildings; if any other form be adopted, more of both materials and labour will be required." Much the best publication on the subject of farm buildings is that of Mr Wauwell, entitled *Designs for Agricultural Buildings*. London. 4to. 1837. It ought to be consulted by every proprietor intending to erect or alter farm buildings. According to this author a farmery ought neither to be situated on a hill nor on a dead flat, but, if possible, on gently waving grounds on a southern declivity. At all events the spot should be dry, and of easy access — dry that it may be warm and easily kept clean — easy of access and egress, to facilitate carrying hence the crops, and out the manure, and for general despatch of business. It should not be far removed from a public road, and should, if possible, command a view of the greatest part of the farm. The site to be built on should be level, or made so, or nearly so, declining in preference to the north. Drainage must be got, or a deep cesspool formed for the house; and a strong pit for the dairy-garage. A gravelly soil, on the banks of a quick-running stream, is one of the best kinds of situations; while a rich and marshy soil is the reverse, and peculiarly unwholesome. Plenty of good water is desirable; and if that cannot be got otherwise, it must be obtained by a mode which never fails — "by putting spouts round all the buildings, to collect the rain-water which falls upon them into one, two, or more tanks by this last means a sufficient supply of water has been collected from the roof of a cottage to answer every purpose of the family during the drier seasons, while other cottages in the neighbourhood, having only ponds, had to travel miles for water. Ponds having a large surface exposed to the sun and air — even lose a great proportion of water by evaporation; the water in a covered tank is not liable to this loss, and will keep quite clean, and, if properly ventilated, will always be sweet. The quantity of water thus falls annually upon every hundred superficial feet of surface of building, is about 1,400 imperial gallons. Besides the water collected from the buildings being useful, the buildings themselves will be benefited by the spouts, as the walls and their foundations will be kept much drier, and will last longer than they would do if all the water from the roofs were suffered to fall upon them." The manner of constructing tanks will be found in Part III. Book III.

Chap. III. Sec. III. The aspect, or principal front of the house, and that side of the farm-yard which is least threatened by buildings, should generally face the south. "As the wind rarely blows from the south-west, and as our most violent and most violent winds are from the south-west, it would seem that the best side of the house will generally be the best aspect." The north-east corner being the coldest, is the best for the dairy. Open cattle-sheds should face the sun. The farmhouses should be at a little distance southward from the middle of the south side of the farm-yard. The living room and the master's bedroom should look into the farm-yard for the sake of looking after the servants, and seeing that no accident happens to the live stock. The rule for the distance of the dwelling-house from the south wall of the farm-yard, is the length of the house's shadow at noon on the shortest day. "In the latitude of London, the length of shadows on a horizontal plane when the sun is in the meridian, on the shortest day is about equal to 3½ times the height of objects. On the 23d of November and 10th of January they are equal to three times the height. The back of a farmhouse in front of the yard ought not, therefore, to be placed much nearer to the south side of the farm-yard, than four times the height of the house." It is essentially necessary for the health of the inhabitants, that the house should be separated from the farm-yard which is generally covered with dung by an open, naked, and dry court-yard; since nothing is more injurious to health than putrid effluvia of every kind besides, bad smells, it is well known, "lessen the products of butter dairies by preventing a complete separation of the cream from the milk." Hog and poultry houses should be near the kitchen and the brewhouse, but not so near as to offend by their smell. The barn and threshing-machines should in general be placed on the north side of the yard; the granary over the straw-room, the stables, cow-houses, and cart-sheds, on the east and west, and the open sheds on the north side, so as to face the south.

2922. *The form and proportion of farm buildings* are ably treated of by the same author. The more a building deviates from a square, the more will it require to enclose a given area. The area of a building twenty feet square, is four times as large as that of one ten feet square, and it only requires twice the length of wall to surround it. Hence large and houses cost less proportional expense than small, roomed ones. Utility, durability, and economy are best obtained by adhering strictly to simplicity of form, and building with good materials. Let the buildings be quadrangular or nearly square as other circumstances will allow and roofed at one span. Avoid lead gutters, and such projections as bow windows, dormer windows, &c. These are not only expensive to construct and keep in repair but are often the cause of much damage to other parts by the overflowing of water particularly after snow. The increase of the size of farm houses is not required to be in the same ratio as the extent of the farms; that is, the dwelling-house for a small farm must be proportionally larger, and consequently will cost more, in proportion than one for a large farm. The cost of cattle-sheds, cow-houses, and stables, will be nearly in the same ratio as the size of the farms, provided the lands be of the same quality and in like situations. One window will generally be found sufficient for every room in a farmhouse; unless where two would admit of looking over a greater part of the farm. Every window ought to be made to open at top and bottom for the purpose of ventilation and the top ought to be as near the ceiling as possible for that purpose and because the upper half of a window always admits most light. All rooms should be high, because the floor and ceiling cost the same, whether the walls are high or low. In all new buildings, bedrooms, in addition to the chimney for the fire, should have a small flue say six inches square, carried up from the top of the room in any convenient situation, for the purpose of ventilation; cellars, and even stables, and cow-houses, should be ventilated in this way. This has been done by many gentlemen in their stables, because, as our author remarks, the health of servants is often less attended to than the health of cattle. Farmers and their families frequently suffer in their health without knowing the reason from the pernicious effluvia of the following articles — Oil, oil colours, impure wool, sweaty saddles, soap, tallow fat, fresh meat whether raw or dressed, wet clothes, and other wet articles, by foul linen, washing, drying, and mending; by the fumes from the charcoal fires, which are extremely pernicious, and frequently fatal, by green plants and flowers, however fragrant, and by mignon and hops; which last articles, Dr Wallich says, have also sometimes proved fatal. The doors of all dwelling-houses ought to be raised above the surface, not less than eighteen inches on a damp soil, nor nine inches on the driest. No external walls to dwelling-houses should be less than a brick and a half in thickness, unless cemented on the outside or built with Roman cement.

2923. *The conveniences of farmhouses and detached offices* are arranged by Weistell under seven classes as follows —

2924. 1st Class. *Bak kitchen, bacon-room, bakehouse, brewhouse, cider-house, kitchen, and washhouse.* Two rooms generally serve for all these purposes in farmhouses of the smallest size; but the bakehouse and the brewhouse should always be in detached buildings, as the vapour arising from both baking and brewing is very injurious to health. Bacon is best kept in a closet with a draft through it.

2925. 2d Class. *Cellar, potato-place, carrot-store, &c.* When under the kitchen they should be arched over; when sunk only a few steps, the walls should be built hollow and a bank of earth raised against them.

2926. 3d Class. *Chambers or bedrooms.* Such as are in the roof should be lighted from the gables, dormers being expensive. The men-servants bedrooms ought not to be up the same stairs as the bedrooms for the family.

2927. 4th Class. *Cheese-press house, cheese-room, dairy, dairy-scullery and shed.* These ought all to be connected. "A milk-room, sunk three feet within the ground, and a sloping bank raised against its walls externally to the height of three feet, with the earth dug out of it, will be found nearly as cool in summer and warm in winter as a cellar but more convenient to occupy as four or five steps to descend into it will be sufficient." The milk-house should never be used as a pantry because the stink of milk to the latter prevents the cream from rising. A run of water through a dairy carries heat to it in winter and from it in summer.

2928. 5th Class. *Parlour, counting-house, pantry, and store-rooms.* If the two latter apartments are attached, instead of being within the house, so much the better on account of the pernicious effluvia which proceed from them.

2929. 6th Class. *Court-yard, stable-house, privy, ash-pit, and fuel-house.* A tank may be built in the court-yard for the hog-wash, and it ought to have oak covers, like the water tank. The compost of the privy ought to be lined with Roman cement, and its walls ought either to be hollow or of double thickness. "When a drain is required, it should have a trap from the under side of the seat, a trunk or flue should be constructed to carry off, above the roof, any small dirt that may arise; if, however, the cesspool be situated, so that no air may be admitted below the seat, which always ought to have a curve the air would then be stagnant, and the smell not likely to ascend. The roof-house may also, in some cases, serve for the cheese-press house, and also for dry pigs' food."

2930. 7th Class. *Coal-house, fuel-house, wood-house, and wood or coal yard.* In some places the wood is stacked and thatched.

2931. *The out-offices of farm buildings* are arranged by the same author in eleven classes, as follows —

2932. 1st Class. *Barn, straw-rooms, and threshing-machine.* A comparatively small barn will suffice where there is a threshing-machine. Parallelogram barns (fig. 442.) and barns with pannels (fig. 441.), are much more expensive in proportion to their capacity than square barns (fig. 443.) On the same principle, as we have already mentioned, if all the buildings of the farm were arranged under one roof, the same accommodations would be obtained at much less expense; but among other drawings,

ways there would be no sheltered yards for cattle, unless walls were built on purpose, which would waste-

when this is the case, below the place where the cattle drink, it may have conveyed into it the overflowings and drainage of the yards and offices, after they have been altered through the earth and peat, and thus enriched, be conducted to adjoining meadows, and as much ground watered with it as it is capable of bearing.

5026. 6th Class. *Oxen-houses, feeding-houses or sheds, foddering-hay, bull-house calf-house, hay room, store or barn room, turning-cistern, and place for milk cattle.* No cow or feeding house should be built without a passage or foddering bay at the heads of the cattle. If that be wanting, it not only takes more time to feed the cattle and clean their troughs, but also their food, when passing behind them, is liable to be soiled by their dung, thus renders it highly disgusting to them, which is the cause of much waste. When the cattle stand in rows across the building, one foddering-bay may serve two rows. It should have a gate at each end, and if a stream of water is at hand, it may have a sunk cistern for washing the troughs. Stalls for containing two cattle of the largest size should be seven feet wide and twelve feet long. By double foddering bays and the rows of cattle across the house, more room is got under the same roof, and the cattle are fed with greater facility.

5026. 5th Class. *Stable, stable-court, hay and chaff room, lower hay or house, and harness-room.* The width of each stall should be from five to six feet. Short partitions between stalls from three feet six inches to four feet long partitions eight feet. Boxes for single horses should be eight feet wide and twelve feet long. Rooms may often be made in the walls to contain forks and other stable implements, harness, and to lessen the projection of corn-bins. The height from the floor to the ceiling should be no more than less than eight feet. Laths over stables are laid places for both hay and corn, from the breast of the animals and the effluvia of the dung. For draught horses a stable open to the roof is best. For saddle horses one closed over at nine feet, if properly ventilated, is preferable, as they require to be kept warmer. Small openings should be made at the bottoms of the doors, and at the tops of the walls, with shutters, so as to admit of ventilation when the larger windows cannot be opened. Stables should be exceedingly well paved, because when the urine does not run off, it generates a variety of diseases.

5027. 6th Class. *The cart-shed or wagon-house, plough and harrow place, and wheel-room.* The height should be at least seven feet, and the granary may frequently be built over.

5028. 7th Class. *Hogsties, hen-roosts, fowling-house, duck-house, goose-house, large food-house large food-shed, pigpen-house, poultry-yard, and turkey-house.* The hogsties should be so placed as to be of easy access from the kitchen, and at the same time not to prove offensive to either the house or the stables by their smell. The height may be three or four feet, and the hen-roosts may be placed over them. The better for preparing their food, the food-tank, the duck house and the goose-house near them. The pigpen-house may be placed over any building, but if the water collected from the roof be used for ordinary purposes, pigsties ought not to be kept.

5029. 8th Class. *Drinking-rooms for wheat, and slaughter house.* One building will serve both these purposes, and it should be paved with flat paving-stones.

5030. 9th Class. *Sheep-house.* A square of twenty feet on the side will contain thirty sheep, the walls should be two feet high. This gives 144 feet surface to each sheep. The doors ought to be always open, and there ought to be a fold-yard, so that the sheep may go out and in at pleasure.

5031. 10th Class. *Furze, fuel-house, workshop, privy, &c.* The furze ought to be apart on account of the danger of fire. The carpenter's workshop ought to have sliding doors to admit a cart or wagon. In large farmhouses there ought to be a small yard distinct and apart from the fold-yards and fold-yards, for the purpose of the furze, workshop, implements requiring repair, and stock of timber and other materials. In all farmhouses there ought to be two privies, one for the women-servants near the house, and one for the men near the stables. There ought also to be two water-closets, one in the dwelling-house for the mistress and her female children and friends, and the other within the house, or adjoining it, for the master and his friends.

5032. 11th Class. *Man's lodge, meal-chest, and potato house.* Where single men are kept, they are sometimes lodged in the farmyard, and supplied with meal, milk, and potatoes. They should have a large, light, and well ventilated room for cooking and living in, with bedchambers over and iron bedsteads. The practice of sleeping in lots over horses is highly injurious to health.

5043. *The materials and construction of agricultural buildings* are next treated of by Webster, in a manner at once highly scientific and practical.

5044. *Mortar.* Bad mortar is the main cause of the decay of all our modern buildings, from the cottages to the palaces. Roman cement should be used in foundations, in exterior pointing, and frequently even in plastering in the interiors, in different proportions, according to circumstances which it is unnecessary to suggest to the builder. A cold mix of brackish water and sea sand, drunk the time while it is yet hot from the kiln, makes it into mortar immediately and use it if possible the same day. This applies to all kinds of lime to be used in building. All lime or mortar to be mixed with Roman cement, ought to be used instantly afterwards; if not used in five minutes it will set and become useless. Mortar to be used with hair as plaster may be kept some time, but no advantage is gained from this in point of strength, but the contrary.

5045. *Walls.* Foundations should vary in thickness according to the compressibility of the ground, the height to which they are to be built, and the weight they may have to support. Under wall doors or windows, inverted arches springing from the adjoining plain are found useful, by equalising compression. Walls should diminish in thickness as they rise. Windows and door frames in external walls should always be placed in recesses, and every window should have a sill. Where anything is to be fixed to walls, a piece of wood or stone like a bolt or screw should be built in, having the end even with the surface of the wall. In walls built of brick or small stones, timbers, or plates of timber, stone, or cast iron, should be laid under the ends of all timber beams on the walls to spread the load. In tying all walls exposed to the weather, set the last course in Roman cement.

5046. *Timber.* Soft woods, as the oak and fir, are better for floors than stronger and more elastic timbers, like the ash, which breaks with less weight than these woods. The strength and stiffness of a joint depend more on its depth than its breadth, & that too little attended to by many country carpenters.

**Roofs.** High roofs are necessary for tempestuous climates, the better to shoot off the rain and snow; but a high roof, having a larger surface than a smaller one, requires timber of a greater quantity, to make it equally able to resist high winds; roofs, therefore, should be made sufficiently high for the climate and kind of covering, and no higher. A roof whose height is one half the span, will have one fourth more surface than if it were made one fourth the span. In general one third of the span or width of a roof is the lowest extremity that is advisable where tile, either plain or pan-tiles, are to be used. Plain tiles should be laid dry and afterwards plastered wholly over tiles and batts together, with coarse hair mortar. This is considered a great improvement over the commoner modes, of laying tiles in plaster or in straw. Roofs for pan-tiles in exposed situations should be somewhat higher in pitch than in sheltered places. Roofs for gray or stone slates should be strong in proportion to the great weight of these materials. Roofs for straw, ling, chips, reeds, &c. should be half their width. Roofs of these materials have many disadvantages, and among others, that of sending the water which falls on them unfit for culinary purposes." (*Widdell's Designs for Agricultural Buildings*, p. 73)

**Stall.** For a grander farm in a recumbent position the following plan (fig. 443.) is given by Widdell. The house consists of a fold-yard for the cattle, and a court-yard, to keep the cattle, pigs, &c. from the

443

house, which is placed on the east side. On the ground plan of the house are the kitchen, back kitchen, parlour, dairy, and pantry. Both the kitchen and back kitchen overlook the yard, &c. The other window to the kitchen and also the parlour window, are supposed to overlook the farm. In the back kitchen are shown the situation of the copper or boiler, pump, and sink. The dairy is sunk five steps, for the sake of coolness in summer, and warmth in winter, and the way the benches or shelves may be placed, is shown. The pantry which is down the same steps leading from the back kitchen to the dairy is under the stairs to the chamber floor. Under the parlour is the cellar. A part of the cellar may be partitioned off for a store-room for potatoes, &c. There are, on the first floor four chambers, and over them two garrets in the roof, lighted from the ends of the house. The chamber over the dairy may be used for the man-servant's bedroom, or should that not be required, as it will be lofty, it may be used as a store-room. Next the house, on the north is a stable for four horses. A saddle closet might be conveniently formed in the corner of the stable, at the back of the kitchen fire place, where the saddles, &c. would always be kept dry. At the other end of the stable, a recess is formed for the corn-bin, near the window. The horses, in passing to and from the stable, through the court-yard, do not mix with or disturb the cattle in the fold-yard. The gate to the court-yard is placed as far as possible from the house and posts and rails, or chains, may be placed, as shown by the single line, to keep the horses from and to protect children at, the door. A tank for the hog-wash may be made in the corner formed by the house and stable. The situation for it is shown by the dotted circle. Arranged along the north sides of the yards are the chaff-room next the stable, various closets, open shed, and calf-house. The shed is open to the south and may be used for cattle, and a part of it for a cart. The space within the roof of either the shed or stable, may be appropriated as repositories for such tools and implements as are only occasionally in use as hay-rakes, ladders, &c. To a part of the space in the roof of the shed (which may be enclosed) an opening, or door may be left from the place for fuel. The barn-roost may be in the roof, over the place for ashes, &c. On the west side of the fold-yard are the barn and cow-house, and, as on the farm for which the design is proposed little corn is grown, the barn may occasionally be used as a store-room for turneps for this reason there is a door from it to the folding-bay. The cow-house contains standings for sixteen head of cattle, eight on each side of the gateway, a feeding-house for the like number of cattle arranged in a single row with a folding-bay at their heads, would require one sixth more area, and one fourth more wall. Over the cow-house is a straw room, which may occasionally be filled with unthreshed grain. The ridge of the roof of the barn and cow-house are of the same height, but the side walls of the cow-house are about three feet lower than the side walls of the barn. On the wall, between the fold-yard and court-yard, is placed a large water trough for the cattle in the yard, and for the stable horses. The hogsty is in the corner next the cow-house and in the opposite corner, a court for the store pigs is formed by the post and rail to keep off the cattle, and there the trough for the pigs is placed. The wide door to the barn is made next the fold-yard, but, in some situations, it may be more convenient on the outside, for when the fold-yard is filled with manure, access with a loaded cart to the barn, this way may be difficult. (*Widdell's Designs*, &c. p. 66.) The following is a recapitulation: a, kitchen; b, parlour; c, back kitchen; d, dairy; e, pantry; f, court-yard; g, tank for the hog-wash; h, man-house-stable; i, chaff-room; k, shed; l, fold-yard; m, fold-yard; n, fold-yard; o, house for 16 cattle; p, hogsty and hog-yard; q, water system; r, hog-courtyard; s, enclosed area in front of the house; t, hog-courtyard.

H h

2949. For a small arable and grazing farm, Waistell's farm-house and outbuildings (p. 444.) are as follows:—The house is on the west side, with a porch in front.

Over the pantry may be a convenient store-room. The barn is forty feet long and eighteen feet wide. The cow-house will contain twelve cattle, and there is a loft over it, which may be used for a store of straw, or unthreshed grain. The approach is supposed to be from the east, and the cart-lodge, which is additional, is so placed that it must always be passed as the horses go to the stable, and the granary over it is conveniently near the barn. A roost for hens may be made over the pigsty adjoining the cart-lodge and under the steps to the granary and at the inner part behind the carts, the ploughs and harrows may be placed." The following is an enumeration of the details: a, parlour; b, kitchen; c, back kitchen; d, dairy; e, pantry; f, open shed; g, coals; h, kitchen-court; i, tools; k, ashes; l, harness room; m, five-horse stable; n, hay and chaff house; o, calf-house; p, stable-court; q, cattle-sheds; r, fold-yards; s, hogst-court; t, barn; u, stalls for twelve cattle or cows, with foddering bay in the centre; v, cart-lodge with granary over; w, hogsty; x, hog yard; y, cisterns and hogs troughs.

2950. The particular requisites of a farmstead, Marshall observes, "are as various as the intentions of farms. A sheep-farm, a grazing farm, a hay-farm, a dairy farm, and one under mixed cultivation, may require different situations, and different arrangements of yards and buildings. On a farm of the last species, which may be considered as the ordinary farm of this kingdom, the principal requisites are, shelter, water, an area or site sufficiently flat for yards and buildings with meadow land below it, to receive the washings of the yards; as well as sound pasturage grounds above it for a great-yard and paddocks with private roads nearly on a level, to the principal arable lands and with suitable outlets to the nearest or best markets." The first of which, when wanting in the desired situation, may in time be supplied by plantations and mound-fences; and where there is not a natural supply of water, a well, water-tower, or artificial rill may, he says, furnish it.

2951. For a farm under mixed husbandry, the particulars to be arranged, according to Marshall, may be thus enumerated:—1. A suite of buildings, adapted to the intended plan of management, as a dwelling-house, barns, stables, cattle-sheds, cart-shed. 2. A spacious yard, common to the buildings, and containing a receptacle of stall-manure, whether arising from stables, cattle-sheds, hogsties, or other buildings together with separate folds, or straw-yards, furnished with appropriate sheds, for pas-

"cudicr stock, in places where such are required. 3. A reservoir, or catchpool, situated on the lower side of the buildings and yards, to receive their washings, and collect them in a body for the purpose of irrigating the lands below them. 4. A corn-yard, convenient to the barns and a hay-yard contiguous to the cow or fattening-sheds. 5. A garden and fruit-ground near the house. 6. A spacious grass-yard or green, embracing the whole or principal part of the convenience as an occasional receptacle for stock of every kind as a common pasture for swine, and a range for poultry, as a security to the fields from stock straying out of the inner yards and as an ante-field or lobby, out of which the home-grounds and driftways may be conveniently entered. In respect to the distribution or management of these different objects, he remarks, that in order to make it with good effect, great caution, study and patience are required, that the most may be made of given circumstances. "An accurate delineation of the site which is fixed on, requires," says he, "to be drawn out on a scale the planner studying the subject alternately upon the paper and on the ground to be laid out; continuing to sketch and correct his plan, until he has not a doubt left upon his mind and then to mark out the whole upon the ground, in a conspicuous and permanent manner before the foundation of any particular building be attempted to be laid. It may" he thinks, "be naturally conceived by a person who has not turned his attention to this subject, that there must be some simple, obvious, and fixed plan to proceed upon. But seeing the endless variety in the mere dwelling-places of men, it is not to be wondered at, if a still greater variety of plans should take place where so many appurtenances are required, and these on sites so infinitely various nor that men's opinions and practices should differ so much on the subject, that on a given site, no two practical men, it is more than probable, would make the same arrangement." There are, however he says, "certain principles which no artist ought to lose sight of in laying out" such buildings and conveniences. "The barns, the stables, and the granary, should be under the eye, — should be readily seen from the dwelling-house" and "the prevailing idea, at present, is, that the several buildings ought to form a regular figure, and enclose an area or farm-yard, either as a fold for loose cattle, or where the stalling of cattle is practised, as a receptacle for dung and the most prevailing figure is the square. But this form is, he thinks, more defective than the oval or circle, the angles being too sharp, and the corners too deep. Besides, the roadway necessary to be carried round a farm-yard in order to have a free and easy passage between the different buildings, is inconveniently lengthened or made at greater expense. The view of the whole yard and buildings from the house on one side of it, is likewise more confined." He had formerly suggested the plan of a polygon, or many-sided figure, or an irregular semi-octagon, with the dwelling-house and stables on the largest side, having ranges of cattle-stalls opposite but he has since formed one on the complete octagon (*fig 445*), the dwelling-house (*a*) being on one side, and the entrance gateway and granary opposite, the remaining six sides being occupied by stables and cattle-sheds (*c, d*) and other outbuildings (*e*), a barn and threshing machine (*f*) with a broad-way (*g*) dipping gently from the buildings, and surrounding a wide shallow dung basin (*h*) which occupies the rest of the area of the yard.

Externally is a basin (*i*) for the drainings of the yard and grass enclosures for calves, poultry and fruit-trees, and rick-yard. This is given as a hint to those engaged in laying out and directing buildings of this sort, which they may adapt to the particular nature of the site of such erections.

2952 An example of the arrangement of a small farm-house and offices (*fig 446*) is given by Beaman, which he considers as very convenient. At the north-west corner is the barn (*e*) with a water threshing-mill and a straw-house (*b*), being a continuation of the barn above, for holding a quantity of straw after it is threshed, or hay, that it may be at hand to give to the cattle in the feeding house below. The upper part of this straw-house may consist of pillars to support the roof, with a space of about eight feet between them whereby a good deal of building will be saved. In the floor should be hatches, at convenient distances, to put down the straw to the cattle below. A court for the dunghill (*c*) has a door to it from the feeding-house, and a large entry at the other end to admit carts to take away the dung on the outside of this should be a urine-pit, in the most convenient place according to the form of the ground. A cow house (*d*) has a door also to the dung-court and a calf-pen (*e*), with a rail across to keep in the calves, even though the doors are all open, adjoining. There

are a stable, with a harness-room, and a place

for keeping corn (*f*); a root-house (*g*), over which, or over the barn, may be a granary; a shed for carts (*h*); a place for keeping large implements, as ploughs and harrows (*i*) for keeping smaller implements, as spades, shovels, rakes, forks, &c., and for the reception of old iron and many other useful things that might otherwise be lost or thrown away (*k*); a pond for washing the horses feet (*l*), which slopes down from each extremity towards the middle, where it is deepest, that the horses may easily go in at one end, and come out at the other, with a rail at each end, to prevent their going in during frost, or when not wanted to go in a pump, with a trough for the horses or cattle to drink out of, especially while other water is frozen, or when the water in the pond is dirty (*m*), but, if it can be contrived so that the water which drives the mill may run through this pond, it will be preferable, as being at all times clean and wholesome. One material advantage of this arrangement, Beston remarks, is, that the fodder consumed

upon the farm goes progressively forward from the barn-yard through the cattle-houses to the dunghill, without the unnecessary labour generally occasioned by carrying it backwards and forwards: for it comes from the barn-yard into the barn, where it is threshed, it is then put in the straw-house, and given to the cattle immediately below and, after passing through them, it is thrown into the dung-court. A rack of straw or hay, built behind the stable or cow-house, or in a shed contiguous to either with proper conveniences, will have the same progressive course to the dunghill for, it will be observed, the communication from these is equally easy from without or within the stall across the calf-pen being intended chiefly to keep in the calves, while the doors on each side are open, during the conveyance of the dung that way from the stable to the dung hill.

2953. The ground plan of the dwelling-house to this farmery (*n*) has a dairy pantry and various conveniences behind for keeping swine, poultry coals, &c. The stair to the upper chambers rises from either side to the same landing-place; from which are a few steps up to the chamber-floor.

2954. A convenient Berwickshire farmery (fig 447) has the following accommodation.

note: a smith's workshop detached from the court-yard (*a*) straw-rooms (*b*); barn

with threshing-machine driven by water (*a*); cattle-sheds (*d*); root-rooms and implements, or if preferred, manure (*e*), stable (*f*) fattening cattle (*g*); cart-shed (*h*) cattle-sheds for feeding (*i*); riding-horse (*k*) tools (*l*) single men's room or built (*m*).

2955. As an example of a commodious arrangement for an arable farm managed for a gentleman farmer by his superintendant, both resident at the farm (fig. 445.), we give the following details. The original design will be found in the account of the Marquess of Stafford's

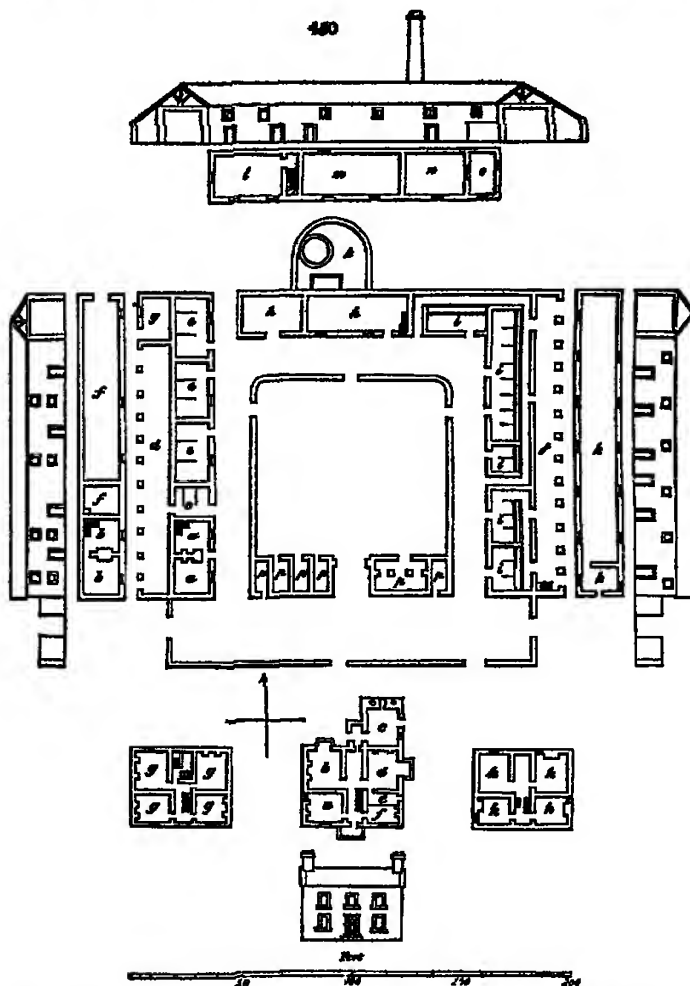

improvements by Mr. Loch a work which, as it contains a great number of valuable plans and elevations, all of which have been executed, may be profitably consulted by every landed proprietor who contemplates either buildings or repairs, and by every architect, builder, or surveyor whose practice is at all connected with agriculture or the country. The dwelling house of the master contains two good sitting rooms on the parlour floor, three bed-rooms on the first floor and stables over them, and over the cellar two kitchen offices. The farmery consists of a cart-shed (*a*) stable (*b*) fattening cattle (*c*) barn (*d*) mill-shed (*e*) cattle-shed (*f*); steaming place (*g*) root-house (*h*); cow-house (*i*) fattening cattle (*k*) intendant's house (*l* m, n) piggeries (*o*). The intendant's house is situated about three times its height distant from the south side of the piggeries (*o*), so that nothing unpleasant or inconvenient may be experienced either from the noise or the smell of the pigs, or from the general effluvia of the farmyard. This house, like every other built by the Marquess of Stafford, whether for his tenants, cottagers, or servants, exhibits a reasonable attention to the comforts of the occupants, and to the improvements of the age in domestic economy and architecture. In this respect, the Marquess, unlike some other extensive landed proprietors, cannot be considered as in arrears of the age in which he lives.

2265. *As a specimen and very complete design, we give the following* The dwelling-house contains two parlours (figs. 442. a, b); kitchen (c); dairy (d); pantry (e); dining-parlour (f); bedrooms (g, h); cellars (i). The farmery consists of cart-stacks

and granary over (a), riding-horse stable (b) common stable (c); stalled cattle (d); places for tools and other articles of the cattle attendant (e) entrance from the spacious root or turning shed (f) straw (g) threshing-machine and water wheel (h) granaries and straw-balls over (g, i, m), tools and sundries (i), smith's shop (j); carpenter's (k) yard for pigs and cotes (n), place for straw and turnips (o); open yards with sheds for wintering cattle (p), and exterior passage (q). The different elevations of this design here given are on too small a scale to be adequately judged of by a general observer, but whoever has paid a moderate degree of attention to architectural lines and forms will foresee the good effect of the ranges of arcades and pillars, the far-projecting roofs, and the general symmetry and regularity, as far as the requisite attention to fitness for the end in view will admit. We regret we cannot render justice to the author of this design by mentioning his name, and we have even forgotten whether we copied it from the *General Report of the Agricultural State of Scotland*; *The Husbandry of Scotland*; *Leck's Improvements of the Marquess of Stafford*; or one of the *County Reports*.

2957 An example of a very complete farmery, with a threshing-machine driven by steam, as informed by a bailiff for the proprietor, we give that of the Dayhouse in Staffordshire. (fig. 450.) The lands contain nearly 500 acres of mixed soil, and the buildings, besides

the bailiff's house, which consists of a parlour (a), family room (b), brewhouse (c) kitchen (d), pantry (e), milk-house (f) bedrooms (g), attics (h)

2958 The farmery contains the following accommodations. Men-servants' day-rooms (a); sleeping ditto, above (b) hackney stable (c), shed for implements (d); cart-horse stables (e), hay loft (f) tool-house (g) barn and steam-engine (h); seedling and cow tyings (i) turnip-house (j) great granary and hay-room (k), which room is used for the annual agricultural dinner given by Lord Stafford, small granary (l); corn-loft (m) straw-lofts (n, o); pigsties, and hen houses over (p).

451. *Widdell's* farm-house and outbuildings of the largest dimensions (figs. 451, 452.) exhibit a very complete arrangement, and his mode of giving isometrical perspective.

views of such buildings ought to be adopted by every architect (see Chap. III. Subject 3.). The farm-house of this design contains a kitchen (a), parlour (b), business-room (c), living-room (d), pantry (e), dairy (f), store-room (g), and brew-house (h). Adjoining are a place for hogs' food (i), for wood (k), for coals (l), for dust and ashes (m); a chaise-house (n), cart-lodge (o), and tool-house (p). The west side of the quadrangle contains five pigsties (1), a calf-house (2), bay for four cattle (3), store and foddering-bay (4), bay for four cattle (5), the same bays repeated (6, 7, 8, 9); a place for a clover for

washing turnips (10), a bull-house (11), cattle-sheds (12), a gateway from the stable-room (13), straw-room (14), threshing-machines (15), clean corn room (16), unfinished corn (17), horse-truck (18), loose box (19), shaft and hay racks (20), stable for six horses (21), harness-room (22), another stable for six horses (23), saddle-room (24). In the open area are, the horse court-yard (25), three fold-yards (26), the stable-court (27), two clatters for the fold-yard (28), four hog's-courts, with feeding clatters (29), and two tanks for hogwash (30). "On the east side of this design is supposed to be a road, from which there is an entrance to a garden in the front of the house and from this road a gate is also supposed to open into the rick-yard, which is at the back of the cattle-shed, and north end of the barn, through this, to the houses on the west side, pass the carts with turnips and other provender for the cattle."

#### CHAP IV

##### *Fences used in Agriculture.*

2960. *Fences*, next to implements, machinery, and suitable buildings, are in most situations "indispensable to the profitable management of arable land. They are not only necessary to protect the crops from the live stock of the farm, but often contribute, in no small degree, by the shelter they afford, to augment and improve the produce itself. On all arable farms, on which cattle and sheep are pastured, the ease, security, and comfort, which good fences give, both to the owner and the animals themselves, are too evident to require particular notice. And as there are few tracts so rich as to admit of crops being carried off the land for a succession of years, without the intervention of green crops consumed where they grow fences, of some description or other can very rarely be dispensed with, even in the most fertile and highly improved districts." The same able author complains of the general mismanagement of this branch of husbandry by which means fences not only often become comparatively useless, but even injurious by the space they occupy and the weeds they shelter. This, he says, "is particularly the case with thorn hedges, which are too often planted in soils where they can never by any management, be expected to become a sufficient fence and which, even when planted on suitable soils, are in many cases so much neglected when young as ever afterwards to be a nuisance, instead of being an ornamental, permanent, and impenetrable barrier, which with proper training they might have formed in a few years. (*Sup. Encyc. Brit. art. Agr.*) Fences may be considered in regard to their emplacement or situation, and their form or kind.

##### SECT. I. *Situation or Emplacement of Fences.*

2961 *The emplacement or disposition of fences* on a farm or an estate will depend on the purposes for which they are made. In laying out an estate, their disposition will depend on the natural surface and situation of roads water courses on the lands to be planted with trees and on a variety of other considerations which will come under review in the succeeding part of this work. The situation of fences on a farm depends on a great variety of circumstances, as the extent of the farm its climate whether pasture, arable, or mixed, on the inequalities of the surface on the nature of the soil, on the supply of water and on the course of husbandry to be followed.

2962 In determining the subdivisions of an arable farm, the excellent author above quoted observes, "whatever may be the kind of fence which it is thought advisable to adopt, we would recommend that particular attention be paid to the course of crops which the quality of the soil points out as the most advantageous, and that upon all farms, not below a medium size, there should be twice the number of enclosures that there are divisions or breaks in the course. Thus, if a six years rotation be thought the most profitable, there should be twelve enclosures, two of which are always under the same crop. One very obvious advantage in this arrangement is, that it tends greatly to equalise labour, and, with a little attention, may contribute much to equalise the produce also. On large farms, where all the land under turnips and clover for instance is near the extremity of the grounds, or at a considerable distance from the buildings, supposed to be set down near the centre, it is clear that the labour of supplying the house and straw yard stock with these crops, as well as the carriage of the manure to the field, is much greater than if the fields were so arranged as that the half of each of these crops should be nearer the offices but by means of two fields for each crop in the rotation, it is quite easy to connect together one field near the houses with another at a distance, and thus to have a supply at hand for the home stock, while the distant crops may be consumed on the ground. The same equalisation of labour must be perceived in the cultivation of the corn-fields, and in harvesting the crops. The time lost in travelling to some of the fields, when working by the plough, is of itself a matter of some consequence

on large farms. > But the advantages of this arrangement are not confined to the equalization and economy of labour; it may also, in a great measure, render the annual produce trifling and equable, notwithstanding a considerable diversity in the quality of the soil. A field of an inferior soil may be connected with one that is naturally rich and in the consumption of the green crops, as well as in the allowance of manure, the poor land may be gradually brought nearer, in the quantity and quality of its produce, to the rich, without any injury to the latter. Thus a field under turnips may be so fertile that it would be destructive to the succeeding corn crops to consume the whole or the greater part on the ground; while another may be naturally so poor, or so deficient in tenacity, as to make it inexpedient to spare any part for consumption elsewhere. By connecting these two under the same crop, by carrying from the one what turnips are wanted for the feeding-houses and straw yards, and eating the whole crop of the other on the ground with sheep, the ensuing crop of corn will not be over-luxuriant in growth on the former, while the latter will seldom fail to yield abundantly. The same plan will also be advantageous in the case of other crops. Hay or green clover may be taken from the richer field, and the poorer one depastured and on the one wheat may succeed both turnips and clover, while the more gentle crops of barley and oats are appropriated to the less fertile field. These observations are particularly applicable to turnip soils, of such a quality as not to require more than one year's pasturage, and which are therefore cultivated with corn and green crops alternately; but the same principle may be extended to clay lands, and such as require to be depastured two or more years in succession.

2963. *Where hedges are employed as fences*, it is of importance that the ditches be drawn in such a direction as to serve the purposes of drains, and also that they may receive the water from the covered drains that may be required in the fields contiguous. According to the greater or less convenience of the line of the fence in this respect, the expense of draining may be considerably diminished or increased.

## SECT. II. Different Kinds of Fences.

2964. *Fences*, as regard to kind, may be arranged as live fences, dead fences, and mixed kinds; but there are four elementary species which are the foundation of all the others the hedge, the ditch, the wall, and the paling. The hedge, when formed of the whetthorn or blackthorn, of the plum or crab, or of the holly is the cheapest, most durable, and the handsomest of all fences on a good deep soil the ditch is the best on low, flat, wet lands requiring much drainage the wall is the best for farming purposes in almost all cases whatever and the paling, whether fixed or temporary (as of hurdles), is the most convenient as a nurse-fence to hedges for immediate or temporary use, and for fencing in parks and scenery where an air of lightness and freedom is a desirable object. From these simple or fundamental fences, a variety of compound ones may be formed. We shall consider them in the order of ditch or drain fences, hedge fences, compound hedge fences, paling fences, and wall fences.

### SUBSECT. 1 Ditch or Drain Fences.

2965. *Ditch fences*, in their simple and original state, were considered rather in the light of open drains than as fences. In a variety of instances, ditches are made for this purpose only, where there is no intention whatever to enclose the field. They are, however, sometimes meant as a fence, but, in such cases, they are made very deep and wide, and the earth taken out of them is sometimes formed into a bank, the height of which, when added to the depth of the ditch, forms a tolerable barrier. In general, however, the ditch is of greatest value when used in conjunction with other fences.

2966. *The form of ditches is various* some of them being of a uniform width both at top and bottom others are wide above, and have a gradual slope downwards a third kind have one side sloping and the other perpendicular. For whatever purpose the ditch is meant, the sloping form is by much the best as it not only costs less money in the digging, but is at the same time much more durable, and has a neater appearance. Where open ditches are indispensably necessary for the drainage of the field, the sloping ditch is preferable to every other as the sides are not liable to tumble in or be undermined or overcast by the current of water, when properly executed. The slope should be considerable perhaps never less than three, nor more than six, times the width at top that it is at bottom.

2967. *The simple ditch, with a bank of earth*, consists merely of a ditch sloping gradually towards the bottom; the earth taken out of it being formed into a bank on one side, leaving a counter-slope, or projecting space, of six or eight inches, on the side where the bank is formed, to prevent the earth from tumbling in and filling up the ditch.

2968. *The bank of earth, with an upright facing of stones, and a slope behind*, is a very common sort of fence, and in some situations extremely useful; in making fields, for instance, for the confinement of sheep or cattle. It is also valuable on the sides of highways, for separating the adjoining grounds, and for laying off enclosures or belts of planting in the middle or corners of arable fields, for enclosing stack-yards, cottages, gardens, &c. The front of the bank is made of a very steep slope with the turf pared off from the surface of the sloping ditch, and the mound at the back with the earth taken out of it.

2969. *The ha ha, or sunk fence*, is calculated chiefly for fields that require no shelter and where a uniform unobscured prospect is an object, as is the case in gardens and extensive lawns but in all situations where shelter is wanted, the sunk fence ought to be avoided, unless a hedge is planted upon the top of it. Sometimes a medium between the sunk and raised fence (fig. 463.) is adopted,

which makes both a durable and unobtrusive barrier

3970. The double ditch, with a bank between (fig. 454) is not often used, unless in cases where it is meant either to plant hedges or trees on the bank between the ditches. Considered as a fence, either with or without a hedge, it is an advantage over the single ditch, as the earth taken out of the two ditches, when properly laid up, will form a bank of a somewhat formidable appearance, which cattle will not very readily attempt to break over.

For the purpose of open drainages it is well adapted, especially by the sides of highways, where the lands have a considerable declivity towards the road. The ditch next the field, by receiving the water on that side, prevents it from overflowing and washing the road,—a circumstance which very frequently happens in such situations while the ditch on the side next the road, by receiving and carrying off the moisture that falls upon it, and which would otherwise lodge there and destroy it, keeps it constantly dry and in good repair. Where double ditches are made in the immediate vicinity of high grounds, or on the sides of highways, care should be taken to prevent the water from the furrows or side drains from running into the main ditch at right angles. Where this is neglected, much trouble and inconvenience arise as when the water comes from a height, sending heavy rains, in a straight line into the ditch, it presses with accelerated force against the sides of it; and if the soil is of a loose incoherent nature, the bank will be undermined and washed away in many places. To prevent this, nothing more is requisite than to alter the direction of the furrows, or small side ditches, at a few yards' distance from their opening into the main ditch.

3971. The double ditch and hedge is now general in many parts of Britain, especially upon what are termed cold lands; from an idea, that a single row of plants would not grow sufficiently strong or thick to form a proper fence. The advocates for this fence further allege that in addition to the two rows of plants forming a more sufficient fence an opportunity is afforded of planting a row or rows of trees on the middle of the bank (fig. 455). This fence is liable to many objections: the expense of forming the ditches, the hedge-plants made use of, and the ground occupied thereby being double what is requisite in a single ditch and hedge. From twelve to eighteen or twenty feet is the least that is required for a double ditch and hedge: this space in the circumference of a large field, is so considerable, that upon a farm of 800 acres, divided into fifteen enclosures, the fences alone would occupy above forty acres. By throwing up a bank in the middle, the whole of the enclosures, not only of both hedges, but also of the row of trees, is confined solely to that space.

which, from its being insulated by the ditches and elevated so much above the common surface, not only curtails the nourishment of the hedges and row of trees, but exposes them to all the injuries arising from drought, frost, &c. The idea of two rows of plants making a better fence than one is certainly no good reason for such an unnecessary waste of land and money; at, in almost every instance, where the plants are properly adapted to the soil and climate, one row will be found quite sufficient; but, if it should be preferred to have two rows, the purpose will be answered equally well with a single ditch, or even without a ditch at all.

#### SUMMARY 2 Hedge Fences.

3972. Hedge fences are of two kinds either such as are made up of dead materials, or such as are formed of living plants of some sort or other.

3973. Dead hedges (fig. 456.) are made with the prunings of trees, or the tops of old thorn or other hedges that have been cut down and are principally intended for temporary purposes, such as the protection of young hedges till they have acquired a sufficient degree of strength to render them fencible without any other assistance. For this purpose the dead hedge is well adapted, and lasts so long as to enable the live fence to grow up and complete the enclosure. In many cases, however dead hedges are had recourse to as the sole fence, and where there is no intention of planting quicks, or any other hedge. From their very perishable nature, however they are found to be exceedingly expensive so much so, indeed, that, after the first or second year they cannot be kept in repair at a less expense than from a fifth to a tenth part of the value of the land, and sometimes more. When dead hedges are meant for the protection of young live fences, if the quick fence is planted upon the common surface, the dead hedge is made in a trench or furrow immediately behind it, in such a way as to prevent the sheep or cattle grazing in the enclosed field from injuring it. Where the quick fence however, is planted upon the side of a ditch, the dead hedge is for the most part made on the top of the mound formed by the earth taken out of the ditch these are called plain dead hedges, being made by cutting the thorns or brush-wood, of which they consist, into certain lengths, and putting them into the earth. We call them plain, in opposition to other descriptions of dead hedges where more art is used such as the dead hedge with upright stakes wattled, and the common planted hedge bound together at the top with willows.

3974. A dead hedge is made in the following manner:—A hedger and an assistant are necessary for this business. The man cuts the stems of the thorns about three feet long with the cutting-bill or axe, as their strength may require, and he lays one out piece above another to form a bundle, taking care to add some of the small twigs to each bundle to thicken their appearance and he then compresses the whole with his foot so that the twigs may stick together. He then makes and prepares several bundles in succession. The hedger takes his spade and, fixing on the part which the line of dead hedge is to occupy he turns up a spadeful of the earth, as whole as possible, as if he were digging a piece of ground of the breadth of the spade. After he has laid this spadeful of earth, so as a bundle of thorns may lean against it in an inclining position, the man hands him one of the bundles over the breast of the hedge with a foot. The butt-end of the bundle goes into the spade-furrow and leans from him against the spadeful which he has placed. The

before than this another method, and places it upon the root of the bundle, and presses it firmly down with the foot, which should be fortified with a wing. He suits the inclination of the dead fence to the quarter whence the heaviest winds prevail, as is invariably done in choosing the position of the stake and fence. In this manner they proceed to form the whole line of dead hedges. As the fence proceeds, the labourer cuts all twigs that have a straggling appearance, with the bill, towards the fence, to give a business and finish to the work. This sort of dead hedge may be placed behind the thorns of a newly planted hedge, much nearer than a paling, as from the breadth of its top, and the sharpness of its angles, so beast can with impunity reach over it, to bite the twigs of the young hedge." (*Quar Jour Agr* vol. i. p. 228.)

2975. As respect to live hedges, they are made either entirely with one kind of plants, or a mixture of different kinds, and for that purpose almost every tree or shrub known in Britain is either wholly or in part employed. The success of every attempt made to rear good fences will be found ultimately to depend on the plants being suited to the soil and climate, the preparation of the soil, the time and mode of planting, the age of the plants, their size, the dressing or pruning of the tops and roots before planting, weeding, hoeing, fencing, and other management.

\*2976. The proper choice of hedge plants is of the first importance. Many failures in this part of the business might be enumerated especially in the more elevated situations, where great labour and expense have been employed to raise hedges of hawthorn, which, after many years care and attention, were found totally unfit for such inclement regions. In such situations, experience has now sufficiently proved that good fences can be reared in a short time with beech, birch, larch, and the Huntingdon willow hedges of these kinds ought, therefore, to be the only ones used in hilly countries, or upon cold wet soils the first three upon the dry soils, and the last, with the addition of poplars, upon such as are wet or marshy. In the low country, however, and in the less elevated parts of the uplands, the whitethorn will be found the best upon all the dry, or moderately dry, parts of the soil; especially the different kinds of loamy, sandy, or gravelly lands upon cold wet-bottomed soils, however, beech, crab, birch, poplar, willow, and alder, may be used with advantage. The birch, poplar, alder, and Huntingdon willow are peculiarly calculated for the coldest, wettest, and most marshy parts, while beech, crab, &c. will be found to answer best upon the stiff clays. Hazel, sweet-briar, mountain-ash, and indeed all the kinds of forest-trees that are at present known to delight in dry soils, may also be successfully employed for making hedges in the low lands but whichever of these is used, it should, if possible, be without mixture. It is seldom that any soil, however good, will be found equally favourable to the growth of plants opposite in their nature: this circumstance alone will render their growth unequal and of course make the fence faulty and defective. These defects in the fence, and inequalities in the growth of the plants, will increase with time, become every day more apparent, and be every day more sensibly felt, as the plants which have thus acquired the ascendancy will continue to keep it, and not only shade the weaker ones, and prevent them from enjoying the influence of the sun and air but also deprive them of nourishment. Independently of these considerations, there is another it is observed, of equal, perhaps greater, moment, that requires to be mentioned allowing the soil to be equally favourable to the growth of the whole plants of which the mixture consists, there are certain plants which are highly inimical to the growth of others, when planted in their immediate vicinity. Ivy and honeysuckle, for instance, when mixed with thorns, or other plants in a hedge, never fail to destroy such of the hedge-plants as they fasten upon. Indeed moss, which is known to be one of the worst enemies to all hedges, is not more dangerous nor more certainly ruinous even the different kinds of sweet-briar, virgin's bower, brambles, briony cleavers, &c. have the same effect and in the end never fail to produce a gap in that part of the hedge where they grow, by smothering the other plants. In general the common hawthorn (*Crataegus Oxyacantha*) is the best British, and we might even say European, hedge plant. The black or alce thorn (*Prunus spinosa*) is perhaps next in excellence, as far as the strength and durability of the fence is concerned; but unfortunately it throws up suckers in such abundance, as to encroach rapidly on the adjoining surface. The common hawthorn, like all plants raised from seed, produces innumerable varieties some of these are much more abundantly furnished with prickles, and some grow much faster than others and it might be desirable to save the seeds of fast-growing prickly individuals in preference to those of such as are less prickly or of slower growth. The smoothest, however, may be considered prickly enough for all ordinary purposes. Like all the ligneous plants of the natural order to which it belongs (*Rosaceae*), the thorn grows readily from cuttings of the roots.

2977. The preparation of the soil for hedges is one of those points intimately connected with, and, indeed, essential to their success. Except in a very few instances, however poor the soil may be, or however strong the cohesiveness of its parts, no attempt is made either to break that cohesion by tillage, or improve its fertility by manuring or alternative manures: the young plants being for the most part laid upon the old surface, which has perhaps never been opened by the labour of man, and their roots covered with the earth taken out of the ditch, consisting very often of the poorest and coldest clay, or of earths loaded with iron or other metallic impregnations. To those who have considered the matter with the smallest attention, the fate of such a hedge will not appear doubtful: the surface upon which the plants are laid will be so hard and impervious to the roots, as

to preclude the possibility of their penetrating it, of course, their only chance of either extending themselves, or procuring nourishment, is by spreading out between the surface and the mound made by the earth taken out of the ditch, or by striking up into the mound, where, though the soil will be sufficiently open to admit of this, the roots, in place of finding an establishment in a situation friendly to their growth, will very often be either starved or poisoned.

2978 With respect to the age at which hedge plants ought to be used, it is very common, especially where young hedges are made with thorns, to plant them of one, two, or three years old, seldom exceeding this last age. Plants of this description, when put into the earth at a proper season of the year, upon land well prepared, if they are afterwards carefully kept clean, and the earth soft and loose, by regular weeding and digging, seldom fail to make good fences; such young plants, however, it is observed, long in a state of infancy, and require great nursing and the most complete protection to bring them to perfection, and are liable to be either much hurt or totally destroyed by many accidents that would produce little or no effect upon older and stronger plants. Much time might be saved in the rearing of hedges, and the fences be much more perfect and useful, if older plants were employed for that purpose. Three years old is certainly the youngest that should be planted, and if they are even six or seven years old, so much the better the prevailing idea that plants of that age will not thrive if transplanted, is totally unfounded. Thorns of six or seven years old, in place of being no thicker than a common straw, will be at a medium more than an inch in circumference we leave those who are judges to determine how far a plant of this last description will be superior to one of two years old, and how much sooner it will answer the purposes of a fence.

2979 In respect to the use of thorns or other hedge plants it may be necessary to observe, that, when the plants are once obtained they should be separated into sorts, according to their size and apparent strength, picking out the largest first, and so on downwards. This will be attended with several very material advantages, which those who have made observations on the subject will very readily understand. Plants of the same size and strength when planted together keep pace with each other, no one of them takes from the earth more than its own share of nourishment, of course the growth of the whole is regular and uniform; and the hedge when arrived at a certain age becomes a substantial efficient fence of an equal height throughout, and free from gaps whereas, when no pains have been taken in sorting the plants, and they are planted promiscuously great and small, strong and weak the consequence is, that the strongest plants very soon outgrow such as are weaker and not only overtop them, but also deprive them of that nourishment which they so much require as the hedge advances in age, the evil becomes greater innumerable gaps appearing throughout the whole line of the fence and small stunted plants intermixed with others remarkable for their strength and luxuriance.

2980 This sorting of hedge plants has a farther advantage namely that of putting it in the power of the person who plants the hedge to put down the large, strong healthy plants upon the poorest part of the line of the fence and to set such as are smaller and weaker upon the richer and more fertile parts. He has it also in his power by a more careful preparation of the soil, and bestowing a greater proportion of manure upon the spaces where the small plants are set to give them that nourishment and assistance which they require, and which would very soon enable them to form a fence equal to the part occupied by the strongest plants.

2981 In regard to the dressing and pruning of hedge plants before they are put into the earth, there is perhaps no part of the system of managing them, or forest trees, more hurtful and defective than that now pursued in the common nurseries. It is a very common practice with nurserymen, in the spring, when they wish to clear their ground for other purposes, to take up great quantities of thorns and other hedge plants, and after pruning the tops, and cutting off nearly the whole of the roots, to tie them up in bundles, and lay these bundles in heaps till they are called for. In this mutilated state they often remain for many weeks, with the mangled roots naked and unprotected, exposed to every inclemency of the weather, before they are sold. In place of this treatment, the defects of which are so obvious, and the consequences resulting from it so hurtful, no hedge plants should be lifted out of the nursery-ground till the day or at most a few days before that on which they are to be replanted and in place of the severe pruning and dressing already mentioned, every root, even to the smallest fibre, should be carefully preserved, and the use of the knife confined entirely to the necessary curtailing of the tops. Where this care is taken, and the plants are put into the ground at a proper season, they will suffer no kind of check, and when the spring arrives will grow luxuriantly and with vigour.

2982 In the after-management of the hedge, complete weeding, loosening, and laying new earth to the roots, for the first three or four years, are indispensable requisites for whatever pains may have been previously taken in dunging and summer-fallowing the soil, unless it be properly attended to and kept clean afterwards, this dunging and summer-fallow, in place of being useful, will prove hurtful to the fence; as the manure and tillage, by enriching and opening the soil, will encourage and promote the growth of weeds which, under such peculiarly fortunate circumstances, will become so luxuriant as either to destroy the hedge, or materially injure its growth, unless they be kept down by frequent and complete cleanings. In loosening the earth about the roots of hedges, whether old or young, it will be of advantage, if there is soil enough to lay up a few inches of it to the roots; this frequently done, encourages them to push out branches near

the bottom, which prevents them from growing thin and open,—a fault to which, if due pains are not taken, almost all hedges are liable.

2363. *On the pruning and after-management of hedges* will depend a very considerable part of their beauty and future value. There is, perhaps, no part of the subject upon which a greater consistency of opinion at present prevails, than the age at which the pruning of hedges ought to commence, the manner of that pruning, or the season of the year at which it may be given with the greatest possible advantage and the least risk the practice with some is, to prune, from the first year not only the lateral branches, but the tops also; they give as a reason, that cutting off the extremities of the shoots contributes to the thickening of the hedge, by making them push out a great number of new ones. The fallacy of this argument, and the mischief with which the practice is attended, we shall afterwards have occasion to notice. As to the manner of pruning, and the form of the hedge, these seem, with many to be matters of indifference no attention being paid to dressing them in such a way as to have them broad at bottom, and tapering gradually towards the top many of them being of one width from top to bottom, and not a few much heavier and broader above than they are below it is obvious that such hedges can neither look well nor be useful.

2364. *The season at which they are trimmed* is in many instances an improper one for, in place of choosing the time when the plants are least in danger of suffering from an effusion of their juices, which is either at a late period in the autumn, very early in the spring or about midsummer the pruning is given late in the spring season, when the sap is flowing the check and injury they must receive from having the whole of their extremities cut off at this period may easily be conceived. In speaking of the treatment of hedge plants before they are put into the ground, notice has been taken of the necessity of preserving the roots as much as possible, and at the same time shortening the tops the latter operation has two good effects by curtailing the top and branches, the roots have less to nourish and by leaving only two or three inches of the top above ground, in place of growing up with a single stem, it sends out two or three and as these strike out from the plant so near the earth each of them has the same effect, and strengthens the hedge as much as the original stem would have done by itself, with this addition, that, in place of one prop or support, the hedge will have three or four.

2365. *After the first pruning* however no hedge should be touched, or at least very gently for some years from inattention to this circumstance, and from the judicious application of the knife or shears at an early period, many young hedges are rendered useless, which, under different treatment would have made excellent fences, with half the trouble required to destroy them. The practice of cutting over the tops yearly which is done with a view to render the hedge thicker and more perfect, is one of those mistakes which we would naturally have supposed common sense and observation would have sooner corrected the effect produced being, in almost every instance, the very reverse of what was intended. Shortening the main stem of a thorn or any other plant makes it throw out a number of small stems immediately at the place where it has been cut and if this operation is repeated once or twice a year, every one of them is again subdivided, as it were by sending out more branches thus in a course of years, during which the hedge makes very small progress upwards, if it be examined, instead of being found to consist of strong vigorous plants, with a good main trunk, each reaching from top to bottom of the hedge, and a sufficient number of lateral branches throughout the whole length of it it will be found, by such repeated cuttings, in the same stunted situation as certain young trees and shrubs that are frequently cropped by sheep or cattle. From the repeated crops of young shoots which the tops send out after every clipping, and the great quantity of nourishment necessary to support such additional numbers, the lateral shoots at the bottom upon the strength and number of which the value of the hedge in a great measure depends, are stunted in their growth, and soon the hedge, of course, becomes open and naked at the bottom, and consequently useless as a fence.

2366. *From the first year of planting, till the hedge has risen to the height of five or six feet*, the main stems ought to be left untouched, and the pruning confined solely to the side branches, leaving them next the root pretty long, and gradually tapering towards the top this pruning of the side branches will make them send out many new shoots from their extremities, which, by repeated trimmings, will become so thick as to fill up every interstice from top to bottom of the hedge while the main stems, by being left untouched, continue their growth upward, till they arrive at the necessary height, when they may have their extremities cut off with perfect safety When a hedge has attained the wished-for height, all that is requisite afterwards is cutting the sides regular with a hedge-bill, preserving it pretty broad at bottom, and drawing it gradually to a point at top this form of a hedge is pleasant to the eye, is well calculated to stand the weather, and becomes every year stronger and thicker A hedge of this sort in full leaf has the appearance of a solid wall and, when viewed after the leaves are shed, presents to the eye a set of many growing piles, so strong and formidable as to bid defiance to any attempts that may be made to break through them.

2367. *In the management of old hedges*, the above directions and observations apply with strict propriety, only to such as have been regularly attended to from the time of their being planted; as there are, however, innumerable hedges in the kingdom, which, by being neglected, have grown up to a great height, have become open and naked below, and bushy and unmanageable at top it is of consequence to point out the means of reducing such hedges to a moderate state, and rendering them useful. This purpose can only be effected by cutting them down, and procuring from their stumps a growth of new shoots, which, with proper management, will soon make a perfect fence. If the fields enclosed by such hedges are alternately in pasture and tillage, the period most proper for cutting them down is when the field is to be

ploughed. Under a corn-crop, the confinement of the stock is no longer an object; and by the time the field is again brought under pasture, the hedge, if properly treated, will have acquired strength enough to become a good fence. This operation is performed in several ways.

2886. *In the first method of cutting over old hedges*, the plants are cut over about a yard above the surface (*fig 437*), and the hedge is left in that state without any other pains being taken with it; if it has originally been good, and the plants thick enough at bottom, this kind of cutting will answer the purpose perfectly well, and in a few years the hedge will, with proper dressing, become both a neat and a useful fence. But in this mode, when there has been a deficiency of plants, and the hedge is cut over in the manner above mentioned, innumerable gaps will appear which, without some art, it will be impossible to fill up. It has also this further disadvantage, that if either horses or cattle attempt to leap into, or out of the enclosure, the sharp points of the stakes are apt to run into their bellies, this accordingly often happens, and many valuable horses and cattle are killed or greatly injured by such means.

437

2888. *A preferable mode of cutting down old hedges is to cut a fourth part of the plants over to the height which the fence is intended to be made* another fourth about six inches high; and to bend down and warp the remainder with the upright stems (*fig 438*.) This method very effectually closes the gaps and opens below and with slight attention soon makes a good fence.

438

2890. *A third way of cutting over old hedges is that of cutting them close by the surface* this practice, when the plants are numerous, and there are no gaps in the hedge answers very well; but when there is a deficiency of plants in any part of the hedge the want will be very apparent. This last mode, though much inferior to the one immediately preceding, is nevertheless greatly preferable to that first described, as the young shoots sent out from the stumps, by being so near the ground, will in some measure remedy the defects occasioned by the want of original plants whereas, when the old plants are cut at the distance of about a yard or four feet above the surface, the young shoots produced by the cutting will be so high as to leave the hedge open at the bottom.

2891. *The last method of cutting down old hedges and which is yet but very little practised, is first to cut them down even with the surface, and afterwards to cover the stumps completely over, with the earth taken out of the ditch, or from the road-side.* When this is carefully done, it is asserted that every single stump sends out a great number of young vigorous shoots, each of which by branching out from below the surface, sends out roots, and acquires an establishment for itself; by this means the bottom of the hedge becomes so thick, that neither sheep, cattle, nor indeed any animal, can break through it.

2892. *In whichever of these ways the hedge is cut down*, the directions formerly given for the management of young hedges should be strictly attended to. As soon as the young shoots have made some progress, the side branches should be trimmed, and the hedge put into a proper shape, preserving it broad and full at bottom, and tapering gradually towards the top. The same caution is also to be observed with regard to the upright shoots, none of which should be shortened till the hedge has attained the wished-for height. It is surprising what close beautiful fences are raised in this way in a few years, from the stumps of some overgrown useless hedges which, at the same time with their being naked below and of course faulty as fences, occupied four times the space they ought to have done, to the great loss both of the proprietor and farmer.

2893. *Filling up gaps in hedges.* When young hedges are planted, if the plants made use of are of a nature suited to the soil the hedge may be kept free from gaps with very little trouble, for that purpose it is, however necessary about the end of the first autumn after the hedge has been planted to examine it carefully throughout its whole extent, take out such plants as are either in a decaying sickly state or those that are actually dead, and fill up the spaces they occupied with the strongest and most vigorous ones that can be found where this care is taken for the first two or three years, there will be no defects in the hedge, which will be uniformly thick and strong throughout. Thus far of young hedges but when old hedges are meant to be cut down, that have many gaps or open spaces in them, so wide as to prevent the possibility of the young shoots filling them up, some expedient must be had recourse to in order to render the fence complete. This purpose may be answered in different ways the easiest and indeed the most common method is, for the hedger, when he comes to a place where any of the plants are wanting, to take one of the strongest plants next to it, and after giving it a gentle stroke with the hedge-bill, to bend it across the opening, and entwine it with the thorns on the opposite side, indeed, as has been already stated, some have a custom of cutting down only a fourth part of the stems, and warping the remainder with these, which appear like stakes driven into the earth. Where the hedge is shortened to within three or four feet of the ground, both of these methods answer pretty well, and the openings, which would otherwise have been left, are in some degree filled up, but when the old hedge is cut close to the earth, other methods of supplying the defects become necessary. One very simple, and at the same time very effectual mode is, first to dig the ground pretty deep with a spade, and afterwards to take two of the strongest plants purposely left uncut, one from each side of the opening, and removing the earth from their roots so as to loosen them and admit of their being bent down, to lay them close to the earth in the opening, they should then be fastened down with wooden hooks or pins, and

entirely covered throughout the whole of their length with earth. Where this is properly attended, the plants so laid down send up a great number of young shoots, which very soon fill up the vacancy: where it is practised upon a hedge that is cut over close by the surface, no other care is requisite but when it is done with hedges that are cut at three or four feet above it, there will be a necessity for placing a temporary paling in the gap, to protect the young shoots from injury till they acquire a sufficient degree of strength. In cases of emergency the stronger roots of thorns and crabs will, if their extremities are brought up to the surface and then cut over an inch above it, throw up vigorous shoots and fill up gaps.

2294. To mend the defects of an old hedge with success, two things are absolutely necessary: the first is, that the whole of the roots of the old plants, which extend themselves into the opening, be entirely cut off the next, that the hedge shall be cut down close to the earth, for at least a yard or more on each side of it. By cutting away the roots which extend themselves into the opening, the young plants are prevented from being robbed of their nourishment; and cutting down the old ones, for a little distance on each side, keeps them from being shaded, and allows them to enjoy the full benefit of the light and air: cutting down so much of the old hedge, no doubt, renders the opening larger and of course requires more paling to supply the defect but this extra expense will be more than compensated by the success with which it will be attended. In many instances, these vacancies are filled up with dead wood; indeed it is a common practice, after a hedge is dressed, to crush the greatest part of the prunings into these spaces, and under the bottom of the hedge, where it is any way open or naked. The most perverse imagination could hardly suppose any thing more absurd; for if it is the wish of the owner that the plants on each side should send out new branches to fill up the openings, the purpose is completely defeated by cramming them full of dead brush-wood, which not only excludes light and air, and prevents the extension of the branches, but, from the violence and injury that is committed in thrusting in dead thorns, the plants are often materially hurt and when this brush-wood decays, the opening, in place of being diminished, is considerably enlarged the mischief is the same where they are thrust under the hedge, — a practice which, when continued, never fails to render it naked at bottom. The use of stones for mending hedges is equally absurd and pernicious.

2295. In every operation of this kind, where old hedges are either cut over or bent down, the ground on each side, as soon as circumstances will admit of it, should be completely dug, cleared of weeds, and the earth laid up to the roots of the plants. It is surprising what numerous and luxuriant shoots the stumps send out, when managed in this way while, on the contrary when these necessary operations are neglected, fewer shoots proceed from the old trunks and, of these few a considerable proportion are choked and destroyed by the weeds and other rubbish in the bottom of the hedge.

### SUBJECT 3. Compound Hedge Fences.

2296. The single hedge and ditch, with or without paling differs a little in different situations the ditch varies in depth and width the thorns are for the most part placed upon the common surface, upon what is termed a scarcement, or projection of six or seven inches on which they lean, and which serves as a kind of bed when they are cleaned, and prevents the earth from the part of the bank above from sliding down into the ditch. Some object to this scarcement, alleging that it increases the difficulty of cleaning the hedge, and increases the growth of weeds both of which statements are correct but to counterbalance them, it is alleged, and with truth as far as we have been able to observe, that the scarcement mode retards the soil better about the roots of the plants. It is a practice in some parts of Norfolk, in planting hedges in this way, to coat the face of the bank and the projection with loamy earth from the bottom of the ditch made into puddle. This acts for a year or two like a coat of plaster, and prevents the seeds of weeds, which may be in the soil under it, from germinating. It also retains moisture, but the difficulty is to meet with a clay or loam that, when puddled and thus applied, will not crack with the summer's drought and winter's frost. Some have applied common lime plaster for the same purpose; others road stuff and some plant in the face of a wall of stones, or bricks, or between tiles.

2297. Stephens's mode of forming and planting the single hedge and ditch differs somewhat from the general practice it is given at length in the *Quarterly Journal of Agriculture*; and as it is most valuable from the minuteness of its details, and their suitability to all countries where these hedges are grown, we shall here transcribe all its important features.

2298. *Implanting.* "Let three poles, made of dry fir to prevent their warping, be provided, of about an inch and a half in diameter and from eight to ten feet in length. Let two end of them be shod with iron, and let them be pointed to one with white and smelt colours, as these colours are best distinguished by their brightness and contrast in a dull day. These poles will serve to run any line straight upon a level piece of ground; but as inequalities in the ground will often occur, it will be necessary in order to surmount them, to have two or three poles more. A strong nail of iron at one end of a stout

line of each party's posts long, and a string-line, as at the other end of it, with necessary. A rule of wood for the line, divided into feet and inches, at intervals of one foot, and a line of wood divided at right angles to the line of it, to give, when necessary, the length of the chain, is next in order of importance. A plane-table, by which to set off the lines of hedges parallel to each other, where this is required, and an iron measuring-chain, with which to mark equal lengths on the parallel lines across the fields by which the position of the lines of hedges is determined, and to measure the whole work when completed, will be found very useful. A few pointed pins of wood, with barbed heads, to drive into the line of the hedge in a curve, such also as to provide. There must certainly be some care in the work to most advantage; and each post be provided with a spike, a hand pick to pick the sides, and a double-headed shovel (fig. 459), to shovel the bottom of the ditch, and beat the face of the hedge-bank. A foot-pick (fig. 460), to raise the heaviest stones that may appear in the road, will complete the above implements necessary for the work. The shovel is one foot broad and one foot long, tapering to a point, with a shaft twenty-eight inches long. The foot-pick stands three feet nine inches high. The tramp (fig. 460 c), which is movable, and can be placed to suit the foot of the workman, is placed about sixteen inches from the point, which is turned, and is inclined forward. The iron is three fourths of an inch in the eye through which the handle passes, and is an inch and a quarter at the tramp where it is stoutest and thickest. The plane-table is useful for squaring the land, when it is to be raised up. The poles are always used for marking off the breadth of the ridges, and the line and chain will be of service in setting off and measuring the same.

**500. Plants.** The plant that is universally used for thorn-hedges is the whitethorn, hawthorn or maythorn (*Crataegus Oxyacantha*). Thorns ought never to be planted in a hedge, till they have been transplanted at least two years from the seed-bed, when they will have generally acquired a girth of one inch, and about fifteen inches of length, the stem from root to branch being about six inches. As thorns are always planted too thick in nursery beds, in order to save room and draw them up quickly, I would advise their being got from the nursery at that age, the year before they are intended to be planted as a fence, and planted out in beds of ample space in any garden or spare piece of ground where the soil is deep and free. By this process the stems will acquire a cleaner bark and greater strength, and the roots will be covered with an additional number of fibres, the constant effect of transplanting being to cause the production of numerous short fibrous roots. The freedom and celerity with which the plants will grow after the preparatory process, will amply repay the additional trouble and expense. But whether they be kept another year in the ground before they are planted or not, they should be immediately loosened out of the bundles of 500, in which they are sent from the nursery and laid out in rows on the earth in a convenient dry part of the field, and the earth well heaped about them to prevent the fibres being injured by the frost.

**501. Preparation of the ground.** It were unreasonable to suppose that hedges will grow luxuriantly and soon become fences, if the ground on which they are to grow be not previously prepared for their reception. If they are to be planted on land that has been under the usual rotation of cropping on the farm, no further preparation is necessary as to following and cleaning it. If the line of hedge runs along or parallel to the ridges, the best period to commence planting is the rotation, as when the top-ground is to be broken up for oats, as the ground makes the finest hedge-bank, and no protecting fence will be required on that side till the field is again laid down to grass. But should the line of hedge run across the ridges, at whatever angle to them, the furrows will have to be made up to the level of the crown of the ridges, and the unequal shrinking of the earth in them will cause the beautifully continued line of hedge to be unequally depressed at the furrows, and much trouble, and, of course, expense, will be thereby incurred, in making drains to let off the water in each furrow through the hedge-bank, should the ground slope to the bank of it. In such circumstances, I would advise the delay of planting at that time, and to wait till the land is followed and laid down again to grass, when the space for the line of hedge can be raised up longitudinally to the breadth required, the ground on each side of this hedge-ridge then forming the head ridges of their respective fields. The delay thus advised on this particular line of hedge need not cause any delay in the period of fencing the whole farm, for a line in another field, which is to be broken up from last, and along the line of which the hedge is to be run, may be taken in the mean time, as it is certainly not essential to the well-being of the hedges, that the fencing of a farm be begun on one side of it, and carried successively through every adjoining field. It is much better to fence a farm by fields which are ready for the work, taken promiscuously, than to run the risk of crossing furrows with a hedge-bank, which from the nature of ridges, will inevitably intercept surface-water, the injurious effects of which will soon appear upon the growth of the young hedge, in the shape of mildew and fog. Should an old turf wall, or the site of one, cross a line of hedge, every particle of the old turf must be removed, and fresh earth from the field, or elsewhere, brought in its place, for no kind of treatment will render for a great length of time, the soil of an old turf-wall congenial to the growth of thorn plants. Indeed, so I pressed am I with the truth of this opinion from their experience, that should the line of hedge coincide with the line of an old turf-wall, I would advise that the line of hedge be bent up much as to avoid it, or, what is better and better looking, that the whole line of hedge be put as much in advance or retreat of the originally intended line, as to avoid the turf wall altogether. Whether the stamity of the soil from old turf-walls arises from its excessive dryness and pulverization, I do not know, but such soil is no sooner manured or limed, than the moles immediately commence their operations, and turn the whole of it inside out. It is known that manure will not combine intimately with soil in such a state, and perhaps its confined heat in the frosty soil may encourage the hatching of the larva of insects, in quest of which, as food, the moles, "that mining race," as Cooper calls them, — set so earnestly to work.

**502. Division of the line of hedge.** Lines of hedge passing through cultivated land, in a north and south direction, should run in straight lines, and parallel to each other, by which means all short ridges unequal in length, and the ploughing of which consumes much time, will be avoided in every field of the farm, except those which are at its extreme end and head of hedge, which are drawn east and west, on the axes of undulating ground, on which situations hedges form the most effective shelter should also run straight, and where these two lines intersect each other and where, of course, the corners of four fields will meet, a space should be rounded off, and planted for ornament and additional shelter at little sacrifice of ground. (fig. 461.) Some may object to the formality of such things, but they look well, and, as a shelter, there are undoubted to be exposed situations, where only they should be met. Personally, however, I never yet heard of keeping any where, in so artificial a thing as a cultivated farm. Lines of hedges which lie in an east and west direction need not necessarily be made straight or parallel to one another, at least the same strong reason, to save time in work, does not apply to them, as to those which are parallel to the ridges, which are necessarily made to run north and south, for reasons well known to farmers. Indeed, the best of a hollow piece of ground, parallelism in fencing is impracticable, in the hedge-ditch must follow the "devious course" of the hollowed line of land, as

Should a hedge be desired to fence round a rough, mossy, or rocky part in a field, or along the edge of a moor or plantation, let it be planted on the cultivated ground only; the sloping up of the ground

upon the thorns, they are in safety from the frost; but as it is not safe at any time to frosty weather to leave them, for even a night, with thin crusts; for the plants may not only be frosted in the night, but the crust may be put in such a state by the frost as to be unfit for working the next day; and should the frost afterwards continue so hard as to prevent working altogether, the plants thus left exposed will inevitably perish. The plants may be laid another length or two of the cord, if the weather appear favourable, and the plants be quite well, before any more of the ditch be removed, as the last operation on the ditch and bank will be more uniform, and look better when a considerable length of it is finished at the same time, than when joinings are visible at short intervals; but in frosty or very wet weather, the corner a piece of it is better, the better it is for the labourer and the work itself. This concludes the second part of our work, and its effects are represented by the annexed figure (465), exhibiting the laid plant (a) and the broken part of the earth (b). When the work has proceeded to this length the other implements come into use. If the substance of the ditch be a tenacious or ductile clay without any admixture of small stones, the spade should be used for removing it, as no picking is generally necessary in such circumstances; especially if there be any water in the ditch; but if it consists of hard clay rammed with small veins of sand, and intermixed with unbroken small stones,—which composition forms a very common

material,—picking is absolutely necessary and in such matter the spade alone cannot be made to work with effect. Let, then, one of the men with the foot-pick loosen the substratum, as deep as he can reach for the trowel, going backwards, and leaving the loosened material before him. Let another take his spade, and dig up what has been loosened and throw it upon the top of the mould above the thorns, taking care to place the soil so close up continuous with the face of the bank, and bring it up at the same time near to its inclination backwards. Throw some also to the back part of the bank, as to cover the whole bank mould, and endeavour to make the shape of the bank quite uniform all along the right management of which devolves upon this labourer and upon which much of the beauty of the work depends. He must go backwards upon the loosened soil, and pare down the side of the ditch next his right hand, which in this case will be the opposite one from the hedge. If there is more earth at one place of the ditch than another which will happen where there are inequalities in the ground, the surplus soil should rather be thrown to the back of the bank, than the top of the latter be made higher at one place than another; or it could be wheeled away to a spot on which a deficiency of the soil is apprehended. Let the hedger follow with the ditcher's shovel, and throw up all the mould- and which has been left by the men before him, going forward upon his work, face to face with the other man, and leaving the ditch behind him completely finished. He will take care to throw the soil rather full on the face of the bank, even though some of it should trickle down again into the ditch, rejecting all the larger stones that may come in his way and beating with the back of the shovel the whole face of the bank, and smoothing it downwards from its top, to as far as the black mould is seen down the side of the ditch, giving the whole of it a uniform inclination upwards and backwards, as if the side of the ditch were produced. If going over the ditch once in this manner finishes the work, the soil will have been in a friable and easily worked state, but in hard substrata this cannot be the case. The hand-pick is almost always required to raise four or five inches more of the bottom of the ditch in the accomplishment of which the same process as to the arrangement of the men, and the kind of work to each will have to be gone through as described above. In this case, when the picking is proceeding, the hedger must again tread down the top of the bank, before throwing up more soil. This description proves the necessity of projecting the thorn-plants but a very short way out of the bank, as the necessary beating process on its face would otherwise wound them. The beating is absolutely necessary too, in order to produce a skin, as it were, on the face of the bank, which will prevent the frost from striding and trickling down all the due mould-soil with which its whole face is covered, down to the first earth of the substratum in the ditch. This covering of clay and the poorer it is the better for the purpose is, fortunately extremely inimical to the vegetation of small seeds, which would otherwise take root upon the mould, grow up, and either create great trouble to eradicate them, or injure the vegetation of the young hedges. Instead of permitting the plants to project too far out, I would prefer their being nearly buried in the bank, so that the young sprouts had to be relieved in the manner afterwards described, but, in most cases, the force of vegetation itself would easily accomplish this. The state of the work will appear thus in the annexed figure (466). While the two men are preparing the rut and cord, &c. to begin another sketch of it, let the hedger take the shovel, and push back from the top of the bank three or four inches of its crest, or more or less if necessary in order to make the intended top parallel along with the line of thorns, and let him beat the top gently in a rounded form, as in figure 467; which last touch finishes

the whole process of planting thorns.

3006. *Dimensions of the ditch.* The rule observed for the depth of ditch is half its breadth, and the breadth of bottom about one sixth of it, so that when the breadth is four and one half feet, as we have supposed, the depth will be two feet three inches below the surface of the original ground. The hedge-bank is always broader than the ditch, and, in this case, will be five feet; and, of course, the perpendicular height of the hedge-bank, especially after the crust has been rounded and beaten down will be something less than the depth of the ditch. These are, in general, very desirable dimensions for a hedge ditch and bank, when no constant run of water has to be accommodated; but should a stream of water run along the ditch, though in winter only the ditch should be made proportionally capacious; for, if not so made at first, the force of water will soon make it so for itself, and probably endanger the thorn-bed. Should the quantity of earth thrown out to accommodate the water make the hedge-bank too high, part of it should be shovelled back, as it is not desirable to load the young thorns too heavily with a superabundant load of earth, so as to exclude the action of the air from the roots.

3005. *Avoiding obstacles.* Hitherto all our work has been quite smooth; no obstacles have presented themselves to frustrate our designs; but there will be met with sometimes, and we must, therefore, be prepared to avert their injurious effects. These obstacles generally consist of large stones, unequal ground, and surface-water. Landish stones are often found in such situations as we have been describing, and when they can, they ought to be removed, and the foot-pick will be found a most efficient lever for that purpose. Some stones are so large and anomalous, that it is impossible to remove them without the assistance of gunpowder; but blasting isolated masses of rock, whose structure is unknown to ignorant men, is a dangerous business. If they lie across the ditch it must be taken round them, and its sides as shored and pored as to permit water to descend under them, they will do no harm to the thorns, but should the mould be thin over them, an additional thickness of soil must be placed, to form the thorn-bed above them, though this should come an elevation there above the general line of hedge. With regard to inequality of surface, wherever the general top of the ground is in one continued declivity to the line of hedge, and yet the undulations on its surface are so deep as that water could not run in the bottom of the ditch in the general dip of the ground, but would collect in the hollows, were its bottom made parallel to these undulations, the elevated part of these inequalities must be cut deeper, and the hollows less deep, than usual, so that a common level may be obtained by the bottom of the ditch, to give room to the water. A very

best soil, which would make a hollow between the plants and the sloping bank? This hollow would intercept any drops of rain that fell on the bank to sink gradually into the roots. If the soil is being cleared for a thorn, it must be of a singular constitution. The ground that the trees of the forest being cleared afterwards, will be made impervious to water; and as the same thin stratum of it to be made as impervious as possible, for a shelter to the young plants. — A position well adapted to three of water. The thorns have no good reason for showing their heads above the ground, as they might as well be planted, like all other plants, deeper, if, as he thinks, they would sooner become a forest; and, indeed, suggests that thorns do not high hedge by planted in this way. He also recommends the plants being placed one inch separating from the side of the bank. In the method of planting hedges as fully described above, the arrangement is different with, for this sufficient reason — that it would become a receptacle, a perfect hot-bed, for weeds, and if very great vigilance and trouble were not expended in keeping them down, they would inevitably choke the young plants. Along the sides of public roads these arrangements are frequently made for the benefit of the people. The facing of the bank next to be cleared, to prevent the frost shoving the earth of the plantation, which had been put up to hinder the growth of weeds, and all the heating that can be given to it, will never make it entirely impervious to rain. Besides, there is no need of rain entering them, when the back of the bank is composed of loose earth, through which it can easily percolate to the roots immediately below. Nor can such a mass, whatever be its shape, be any protection to the young thorns from any heat, either from behind or below; its mode was being to admit the ditch being made of a sufficient size to carry off water, to afford the hedge roots a covering against drought, and to envelop the black mould which surrounds the roots with a covering of earth, which is itself inimical to vegetation, and which, at the same time, tends to check the action of vegetation in the black mould. Thorns will, no doubt, grow in an upright position as well as in a sloping one, but the latter position is the most convenient for planting with method and dispatch, and in this position the whole stem is converted into root. The transplanting of old thorns to any great extent is, I think, a hopeless task. Besides where are they to be obtained in quantities sufficient to fence a farm? The projecting of the thorn-plants from the face of the bank is a bad plan, as they are not only liable to be wounded in the working up of the face of the mound, by the rolling down of the earth and stones, and by the process of heating and smothering, but when stones spring up from their extremities, and the wind moves them about, the tops exert a lever power on the roots, and loosen it in the soil. Hence, when a thorn-hedge is examined in the first year of its growth particularly in the autumn, when the stems are strong and leafy and the winds prevail, it is often observed, that all those plants, which have been accidentally left projecting further out than the others, have worked an upright oblique hole about them in the earth, whereas all those which have been left even with the face of the bank, or been relieved from some stinging earth, by the force of vegetation, or the hand, are quite firmly embedded in the earth — a state without doubt, much preferable to the other.

3010 *Management of the ditch and thorn-hedge.* The implements necessary for the proper management of hedges are — A common Dutch hoe, 7 inches broad and 5 feet long, for cleaning (A) (see 469.)

A hedge-spike, 5 or 6 inches wide at the mouth and about 3 feet 3 inches long altogether for cleaning (B). A hooked headed stick, for forcing the earth from the points of the earth (C). A switching-bill, blade 9 inches long and 1½ inch broad shaft 3 feet 5 inches long, and weighing altogether about 3½ pounds (D). A fence-cutting-knife, which resembles the switching bill, but considerably stronger and of course heavier. A cutting-bill, blade 7 inches long and 2½ inches broad shaft 2½ feet long and weighing altogether about 6 pounds (E). A light axe, weighing about 3 pounds, and a shaft 2½ inches long (F). A shaft 2½ inches long (G). A shaft 2½ inches long (H). A shaft 2½ inches long (I). A shaft 2½ inches long (J).

3011 *Releasing the buds on the points of the stems.* The first attention which a young hedge requires is to release those buds which may have been prevented by the tenacity of the clayey earth from pushing out, and this is done either by the finger or a small piece of stick, but great care must be taken that none of the sprouts be broken off in the work. The force of vegetation will generally accomplish all that is required, but in some cases assistance is beneficial to the plant.

3012 *Cleaning.* If the hedge has been planted in the autumn, the grass between the inverted soil and the original surface will have decayed so much, as to create little trouble in the early part of the season in clearing away grass. Indeed, both the hedge and bank will not be injured by those plants that may have sprung up from the seed, as they will rather ward off the effects of frost during winter. If they are, however, likely to smother their own seed, it would be prudent to remove them before that time. Should the hedge have been planted in the spring, the vernal influences will keep alive the grass under the inverted soil, and it will grow rapidly so that it may be necessary to clear it away about midsummer at least, in order that the luxuriance of its growth may be checked. The space between the inverted soil and the original ground is the only very troublesome place of the hedge-bank to keep clear of weeds, but even that is six inches below the thorn bed; and if the ground had been properly cleared of quack-grass, couch-grass, and knot-grass, before the hedge was planted, which it ought undoubtedly to have been, the other kinds of weeds which will spring up will be easily got rid of. Couch-grass, when it gets unmanageable about the roots of a young hedge, injures its growth very much, and it is, in such a situation, quite impossible ever after to get quit of it altogether. When cleaning is to be performed, it is done in the following manner — Let the hedger — for one man is not only necessary — take the wing-spike, and hold it in a horizontal position with both hands, the right hand upon the handle. Let him stand in the bottom of the ditch, with his face towards the hedge, and begin to cut away the grass under the line of hedge, with horizontal strokes of the spike, making progress up the ditch with his left side forward. Let a woman place herself upon the top of the bank, with her face also towards the hedge, and with her right hand upon the handle, and with her left foot on the top and face of the bank behind the hedge, and there nimble and dexterously by a peculiar twist given to the line by the wrist, enfold the weeds, and raise as little of the earth as possible. She progresses on the top of the bank with her right side foremost. One or two women, according to the quantity of work, follow with the crested spike; and, stooping in the ditch, pull out the fanned weeds from between the thorns, and all that may be growing where the wing-spike and handle have cut away. In the manner the cleaning process is carried on with great dispatch. The man that is for the second work to do, but even he will move on rapidly if the grass is not allowed to be too old before it is cleared away. After all, it is very evident that a hedge requires to be so thoroughly cleaned in the first season; but in the second year it is absolutely necessary to be very vigilant in keeping early to work, before vegetation is much advanced. If weeding is delayed all the stems of the weeds take root in the ground, the displacing of them leaves away a great deal of earth from the face of the bank. These as in

so that no wind can shake the plant to injure its roots; and the growth of the numerous twigs from the branches is so arranged, that weeds over shoulders can do little injury to the whole formation.

473

When stems are planted on a sward, no transplanting is required, because it prevents the scattering away of the earth; but such instruments are necessary for weeds, and it is impossible to dig a hedge thoroughly where they exist, — to "disturb the soil" as they say. Earth, or its sort, from the bottom of the ditch can be thrown upon the sward, to smother the weeds upon them; but the accumulation of earth there must be limited to the height of the stem roots, and upon this earth weeds can, of course, grow as luxuriantly as upon the sward itself. In short, in such a situation, weeds cannot be eradicated. They can be cut over like mown grass, but their roots will ever be ready to spring up afresh in favourable weather. A fence of a young hedge, planted on a sward, will at once show the inconvenience of such a construction for the eradication of weeds (fig. 473).

3015. *Protecting from cattle.* Lord Kames says, "The hedge is fenced from cattle on the one side by the ditch; but it is necessary that it be fenced on both sides. The ordinary method of a paling is no efficient fence against cattle; the most gentle stroke of a rubbing-post, and the vicious break it gives wantonly with their horns. The only effectual remedy is expensive, but better no fence than one that is imperfect. The remedy is two ditches and two hedges, with a high mound of earth between them." We are left to infer from this, that a paling is no protection to a hedge — two ditches and a mound of earth are. Other writers nearly hold the same opinion. It is astonishing to see persons who pretend to know the practice of husbandry assert the hedge-ditch, or a mound, or a ditch of almost any dimensions, will protect a young hedge from the depredation of cattle and sheep. If such notions at all prevail among proprietors and farmers, it is no wonder that these hedges are so often seen in a ruinous state. If a good paling is not a sufficient fence against cattle and sheep, it is not a ditch or two, nor a mound, that will prevent these committing depredations. If "two ditches" are to be fenced they will require as much paling as a single hedge before and behind, besides the additional quantity of ground occupied by fencing. If gates cannot be prevented in hedges but by double rows of thorns, their owners must be negligent hedgers indeed. As to making a rubbing-post of a paling rubbing-posts ought to be erected in every pasture field, and then neither the "gentle" nor the "vicious" cattle will ever have occasion to use a paling, which is at least a very inconvenient "rubbing-post." The truth is, a fence, of whatever nature it may be, is absolutely necessary on both sides of a young thorn hedge if that hedge separates fields that are to be pastured — and what that fence may be made of depends, of course, on the nature of the materials which are most easily obtained for the purpose.

3016. *Protecting by a paling.* If well-grown Scots pine of eight inches diameter or wealdings of larch plantations, can be procured at no great distance, or grow upon the property that is to be enclosed, better materials for temporary fences need not be wanted. The Scots pine of the above size will cut up into six deals besides the outside skin, and divide again up the middle for rails of perhaps twenty-four feet long or twice up the middle, at right angles, for stakes, which should be sawn across, and pointed, four and a half feet in length. These stakes should be driven at least one foot from the edge of the ditch, by a mallet, into holes formed by the foot-pick at a distance from one another not exceeding five or six feet, fifteen inches into the ground, and which will make the fence stand three feet three inches high. Two of the rails are sufficient for fencing cattle, but three are necessary to keep in sheep. To give additional strength to the fence, the rails should be placed on the face of the stakes next the field, and made to pass each other's ends, so that all the ends of the three rails should not be nailed on the same stake — nor should the root or thick end of the rails be nailed together even after being thrust by the sides, but top and bottom ends nailed together alternately, as this plan equalises the weight of the rails upon the stakes. The upper rail should be at the height of the stakes — the upper edge of the lowest one nine inches, and that of the middle one twenty-two inches, from the ground, as the best arrangement as a fence for sheep (fig. 474). The best nails for such a purpose are called "sout paling-nails," three to three and a half inches long, made in Scotland — for it seems the nails manufactured in

474

the sister kingdom are not in good repute here. A similar fence may be erected on the sides of the bank behind the hedge — but it is necessary to keep in remembrance, that it should be placed clear of the hedge-mound altogether. There is a temptation to place it upon the hedge-mound, as more space is given to the plough, and shorter stakes will there make an equally high fence — but when a fence is placed so near a young hedge as on any part of the mound, cattle, and particularly horses, after they have eaten their fill of grass, and on Sunday when they are idle, will reach over, and bite off the tops of it, as if delighting in mischief, to the serious injury of the young hedge.

3017. *Protecting by stakes and rice.* (fig. 475). When trees are felled or bought by a proprietor for the construction of paling to fence young

475

hedges, the top stems and branches may be made available to the same purpose, in "stake and rice." The branches should all be cut off the tops of the trees, and their stems, if large enough, converted into stakes of the above dimensions; but as these will not suffice altogether other stakes must be sawn from the hole of the tree. These stakes should be driven into the ground in the same manner, and at the same distance, as recommended for paling — and give them an inclining position upwards, towards the tops of the stakes. This inclination must be away in the direction to which the heaviest winds will blow; for instance, if the space runs north and south, the inclination must be to the south, as the north winds are the most severe; and for the same reason, an inclination to the east will avoid the heavy north-west winds. A strong wind against the top, is apt to rattle and bend them back. A single rail nailed at the top of the stakes, completes the mode of fencing. I may remark, that any brushwood, provided it is so long as to reach from spine to spine, will serve the purpose as well as the tops of trees — at least a mixture of them is excellent. Such a fence requires fewer rails, and less good wood, than a regular paling, and is therefore cheaper; and it will stand an equal length of time; and, indeed, the stakes have less strain upon them, in this mode, than the other, as they have not the weight of the materials to bear, and the waving of the branches prevents them from many accidents to which paling is liable, such as people trampling over them, swinging over of youths rubbing upon them and beating both of them, and the like. This is an excellent fence for sheep, affording them shelter from the sweeping blast behind its main support; still, for this purpose, it is generally placed on the north and east sides of fields — the southern trees, which the greatest winds prevail. There is one, and only one, greater objection to this paling — that being close to the top.

501. Shutting down or breathing over an old tree-honey hedge. (Pg. 47) When the hedge, which we  
 left to grow some time ago, gets heavy in the top, and begins to sag,

477

**Season.** *Seasons of performing the operation.* It should be kept in remembrance that this operation must not be performed during a hard frost. I once saw a very fine hedge trampled over and that part, which had been cut down during a hard frost, did not and out a stem next summer exceeding four inches in length, whereas the parts of the hedge cut by the same hedger in frosty weather pushed up strong and healthy stems three feet high. It was remarked at the time the hedge was being cut down, in frosty weather, that the stroke of the bill made a peculiarly ringing sound on the stems, and that they were as brittle as sticks. This was cut over than in frosty weather. Notwithstanding these peculiarities, I am not so anxious of an injurious effect on the growth of the stems as some operators are in seasonable weather: it is astonishing how luxuriant a growth of stems is generally developed. This kind of young hedge is switched and trained in the same manner as described above for newly planted hedges, till it comes to maturity. The hedge should be cut down when the field next the ditch is to be broken up or cut low, as the young hedge will be a fence by the time the field is again in grass. As the field behind the hedge will not lay in the same part of the rotation as the other: it will be necessary to employ the cuttings in some other way. I have seen them used for several purposes, but the most common way requires all the thorn, a part of which may be taken away for other purposes, or a similar purpose in another place. A dead hedge is made in the manner described.

9083. After the stems had a chance to grow smaller and shorter, in the course of year, with this hedge has arrived at maturity. It is found that the stems are no longer so thick, grow twice round from them, and that the bottom of it is too open as a fence for sheep. It will be necessary to cut this whole down within a few inches of the ground, with the axe or cutting-bill, according to the strength of the stem. If the cutting-bill is used, it is managed like the breasting-bill, and at times with both hands; but if the axe, then the builder stands with his feet in an opposite direction to the best cutting one; that is, he keeps his left hand bent the hedge, and using the long-handled but light axe, with both hands, he cuts the thick stems in a sloping direction upwards. It may, in the first instance, be necessary to cut the stems at the branches of the stems, with any instrument with which the work can be done. The axe is best, for, in this process, which requires strength, the gloves are not convenient places of damage. He pulls the stems together, when they are cut, and deposits them on the same side of the ditch as when they were broken over; and it is just as absolutely necessary now as before, to leave the growing stem clean out. Cutting with the axe is a very laborious operation at all times, but particularly when cutting down old thick-stemmed shrub hedges. Old thorns are sometimes so bulky and heavy, that it is necessary to drag them away with horses, instead of attempting to put them on carts. Both after this and the other process, by which the ground around all the roots should be thoroughly cleared of all weeds and it would even be advisable to water-lable the hedge, and to trim the ditch, the work is not yet done. The work of the ditch, there can be no doubt that the ditch will steadily increase, and there cannot be a more favorable opportunity for the work being done, than when the hedge is cut down, either the stone of which the ditch is made, or the ditch can be deepened.

3026. *Rebuilding the old gap of a thorn hedge improperly treated in its youth.* In this operation much care and judgment are required. It is found that in ordinary-sized gaps, which exist between the old stems of a thorn, young plants will not easily take root and thrive. This effect is produced, partly by the shading of the stems which grow quickly out of the old stem and overtop the young plants, and partly by the want of nourishment from the earth, the juices of which have been extracted already by the older stems. To remedy such defects, plashing has been resorted to, and when that has been judiciously done, by laying the plashes near the ground, a small gap may be filled up for some time. But I agree particularly with the following observations of Lord Kinnaird, on the nature of plashing in general:—

3025. "Plashing an old hedge," says his Lordship, "An ordinary practice in England, makes indeed a good interim fence, but at the long run is destructive to the plants; and accordingly there is scarce to be met with a complete good hedge where plashing has been long practised. A cut is laid among the vulgar to have three lives. Is it their opinion that a thorn like a cat, may be cut and slashed at without suffering by it? A thorn is a tree of long life. If, instead of being massacred by plashing, it were reared and dressed in the way here described, it would continue a firm hedge perhaps, for five hundred years." This merits attention. If plashing really be practised, and such an old practice cannot be easily forsaken, it may be necessary to remind the operator to cut the stem no deeper in than necessary to bend it down with considerable difficulty as near the ground as possible; for plashing at a great height above the ground defeats its own object, namely, that of filling up gaps below. Keep the end of the slash down, either by inserting it under a hooked branch of a neighbouring thorn, or by a hooked stick driven into the ground, and push a bit of wedge-shaped stick into the cut, to assist in preventing the slash from starting up. Stuff then some worked up clay into the cut, and thus close it up from the effects of wet and drought.

3026. *Laying an old hedge.* It will be a much better practice to renew the earth in the gaps with fresh soil, mixed with dung and lime in the first year after the hedge has been cut down, and then, in the second year to take a stem from each side of the gap which has shot up from the old stem, and lay them in the soil so prepared, as gardeners lay carnations and roses, by fastening them down to the earth with pins. These layers will strike root, and grow up as young plants; and when they have acquired sufficient strength they then can of course be cut away from the parent stem. When the gaps extend many yards between the old stems, and when of course it would not be practicable to fill up all the space with such layers, the old earth between them must be completely taken out, and new and fresh soil, prepared as above, substituted in its place, and young plants must be laid on a thorn-bed, and the whole work of repair carried on and finished in the same manner as described in the original planting. In training these renewed plants, it will be necessary to check the growth of the old stems, and encourage that of the young plants, till both have acquired the same length, when both may be treated alike. An old gateway may be kept up in this manner, but if still to be used as an emergency, a dead fence of thorns will protect the gap for a great length of time. In repairing hedges, of whatever age, it ought to be kept in remembrance, that a hedge ought never to be planted on the top of a mound thrown up from the ditch. It has, indeed, the advantage of an imposing situation; but being planted in bad soil, and destitute of moisture, it cannot thrive. It is at best dwarfish, and frequently decays and dies. (*Stephens of Bathwick in Quar Jour Agr* vol. ii. p. 321.)

3027. *The hedge and bank* consists of a hedge planted upon the plain surface, with a bank or mound of earth raised behind it by way of protection.

3028. *The hedge in the face of a bank* differs from the former, principally in having the hedge in the front of the bank considerably above the common surface, in place of having it at the bottom.

3029. *The Devonshire fence* is a sort of hedge and bank and as it consists of an earthen mound, seven feet wide at bottom, five feet in height, and four feet broad at top, upon the middle of which a row of quicks is planted and on each side at two feet distant, a row of willow-stakes, of about an inch in diameter each, and from eighteen inches to two feet long, is stuck in, sloping a little outwards these stakes soon take root, and form a kind of live fence for the preservation of the quicks in the middle. This fence nearly resembles the hedge on the top of a bank, and is equally expensive in the erection the formation of the bank deprives the adjoining surface of its best soil, and the plants made use of are liable to every injury that can possibly arise from drought, frost, and gradual decay or crumbling down of the mound. The addition of the willows to this fence is certainly a disadvantage if the quicks require protection, dead wood is equal to every purpose that could be wished or expected, and at the same time possesses the additional advantage of requiring no nourishment, and having no foliage to shade the thorns or other plants.

3030. *In the hedge with posts and rails*, the railings are employed for the protection of hedges, as well those that are planted upon the plain surface, as for the hedge and ditch united. The addition of a paling is, however, more immediately necessary in cases where the hedge is planted upon the plain surface, especially when the fields so enclosed are in pasture.

3031. *The hedge and dead hedge* is a fence that consists of a row of quicks or other hedge-plants, set either upon the plain surface, or in the face of a ditch or bank. The dead hedge answers a double purpose, namely, that of protecting the young plants from the injuries they may receive from cattle or the inclemency of the weather, and at the same time forming a temporary enclosure which lasts till the hedge is grown up.

3032. *The hedge and wall fence* is of two kinds, namely, a coarse open wall, built of loose stones, on the top of the bank formed by the earth taken out of the ditch and when hedges are planted upon the plain surface, a thin and low wall regularly built alongside answers the double purpose of sheltering and encouraging the growth of the plants while they are in a weak tender state, and afterwards prevents the possibility of the hedge becoming open below. Where gardens are entirely, or in part, surrounded by hedges, and in the enclosing of fields by the sides of highways, especially in the vicinity of great towns, where dogs and other destructive vermin are apt

to creep into the enclosures, and annoy the stock, the low wall forms a valuable addition to the fence.

3033. *The hedge in the middle or on the face of a wall is executed in the following manner:*—The face of the bank is first cut down with a spade, not quite perpendicularly but nearly so: a facing of stone is then begun at the bottom, and carried up regularly, in the manner that stone-walls are generally built: when it is raised about eighteen inches, or two feet high, according to circumstances, the space between the wall and the bank is filled up with good earth, well broken and mixed with lime or compost: the thorns are laid upon this earth in such a manner, as that at least four inches of the root and stem shall rest upon the earth, and the extremity of the top shall project beyond the wall. When the plants are thus regularly laid, the roots are covered with earth, and the building of the wall continued upwards, filling up the space between the wall and the bank gradually as the wall advances upwards: when completed the wall is finished with a coping of sod, or stone and lime. When the plants begin to vegetate, the young shoots appear in the face of the wall, rising in a perpendicular manner. This sort of fence is much in use in some of the western counties of Scotland, and wherever there is plenty of stones it is a good and cheap method, especially where wood for rails or paling cannot be got readily (C).

3034. *The hedge and ditch, with row of trees, differs from those which have been described only in having a row of trees planted in the line of the fence along with the hedge.* The advocates for this practice say, that, by planting rows of trees in the direction of the fence, the country is at once sheltered, beautified, and improved: and that the interest of the proprietor is ultimately promoted by the increasing value of the timber raised in these hedgerows. It is also said, that such trees produce more branches for stack-wood, knees for ship-builders, and bark for the tanners, and they sell at a higher price per load, than trees grown in woods and groves. Besides, close pruning hedgerow trees to the height of twelve or fifteen feet, prevents their damaging the hedge: the shelter which they afford is favourable to the vegetation both of grass and corn: it also tends to produce an equable temperature in the climate, which is favourable both to the production of, and greater perfection and beauty in, animals, and of longevity to man. Though the practice of planting hedgerows of trees is very common, though its advocates are numerous, and though these arguments are urged in its favour yet the objections are also entitled to very serious consideration. When trees are planted in the line of a fence, if that fence is a hedge, the plants of which it consists will not only be deprived of a great part of their nourishment by the trees, but will also be greatly injured by the shade they occasion, and the drop that falls from them during wet weather: upon this point little reasoning is necessary: for if we appeal to facts, we shall find that no good hedge is to be met with where there is a row of trees planted along with it. The mischief is not, however, confined solely to hedges: the effects are equally bad, perhaps worse, where the fence is a stone-wall: for though in this case the shade or drop of the trees is hardly if at all felt, yet, when they have attained a certain height, the working and straining of the roots during high winds is such, that the foundations of the wall are shaken and destroyed: accordingly wherever large trees are found growing near stone walls, the fence is cracked and shaken by every gale of wind, is perpetually falling into large gaps, and costs ten times the expense to keep it in repair that would otherwise be required if no trees were near it. Admitting, however, that the trees in hedgerows were no way prejudicial to the fence, which we have already shown is by no means the case, another argument may be successfully used against the practice. It is seldom, indeed, that trees planted in hedgerows arrive at any great size: on the contrary they are generally low and stunted: and while they occasion a visible loss by the mischief they do the fence, their utmost worth, when they come to be sold, will seldom be found adequate to the loss and inconvenience they have occasioned.

3035. *Stephens is decidedly turbulent in planting trees in hedges.* It is quite impossible, he says, even with the greatest care imaginable, to rear thorns to a good fence under street-trees, even trees growing on the top of the mound of a double hedge, abstract the moisture from the earth and injure the foliage of both the hedges: and though it may be probable that the two hedges may not be galled by the trees in places exactly opposite, the injury the individual hedge suffers cannot be remedied under the over-shadowing poison. Lord Kames makes the following judicious remarks on planting hedgerow trees:—To plant trees in the line of the hedge, or within a few feet of it, ought to be absolutely prohibited as a pernicious practice; it is ensuring that people should fall into this error when they ought to know that there never was a good thorn hedge with trees in it: and how should it be otherwise? An oak, a beech, or an elm, grows faster than a thorn: when suffered to grow in the midst of a thorn hedge, it spreads its roots every where, and robs the thorns of their nourishment. Nor is this all: the tree over-shadowing the thorns keeps the sun and air from them; at the same time, no tree takes worse with being overshadowed than a thorn. Hedgerow trees certainly give a closely fenced appearance to a country: and at a distance look not unlike trees in an orchard; but they are at best formal; the trees in them, though they may be very hardy, and yield strong, tough timber: never attain to great size, and are often distorted in shape by the force of the winds, which bend them to their will; and when their baneful effects on the hedges and crops are considered, it is astonishing to see their cultivation so prevalent. It may be ungracious treatment, now that they are planted and growing, to root out every one of them without delay; but they may be treated at maturity whose consumption may be directly wished for: and whose places will not be replenished by similar occupants. Plantations, and clumps, and belts of trees, afford better shelter than single rows; and when they can be judiciously planted, in situations where little use can be made of the

ground for culture—and there is no property without many such situations upon it—and in other situations where they would even date from the previous waste, they not only become useful timber, but ornamental objects in the landscape—objects which fill the eye, fix the attention, and are vastly more valuable than any single row of standard trees can be.” (*Quar Jour Agr* vol 1 p. 683.)

3086. *The hedge and ditch, or hedge and wall, with belt of planting*, in exposed situations, is strikingly useful and ornamental, while upon low grounds it is not only unnecessary, but in many instances absolutely hurtful. For instance, in deep and broad valleys surrounded by hills, and sheltered from severe blasts, belts of planting are not only unnecessary, but even hurtful and ruinous by the ground they occupy, which could certainly be employed to greater advantage, and the original expense of enclosing and planting saved.

3087. *The hedge and ditch, or wall, with the corners planted*, is employed upon some estates instead of the belt of planting. According to some, it has a good effect upon the scenery of the country, and answers the purpose of general shelter extremely well. It is, however, greatly inferior to the belt of planting, for the purpose of sheltering particular fields. But as in every field there is a space in each angle that cannot be ploughed, by planting these spaces, which would otherwise be left waste, many valuable trees are raised with little expense, and with scarce any waste of land.

3088. *The furze fence* may be had recourse to with advantage whenever such plants are found to grow vigorously in a soil. Fences of this sort are mostly made upon mounds or banks of earth, by sowing the seed of the plant. Sometimes the bank is only sloped on one side, but at others on both. In the former case the front is perpendicular and faced with turf or stone. From these fences being raised so considerably above the common surface, they are very liable to injury from frosts and other causes in severe winters. In all cases where they are clipped or cut once a year, or once in every two years, the clippings may be bruised and given to horses or cattle, who are fond of them, and are found to thrive and fatten on this food.

#### SUMMARY 4. Paling Fences.

3089. *Paling fences* are only to be considered in a secondary light; for, of whatever wood they are made, however substantially they may be executed, or in whatever situation they are placed their decay commences the instant they are erected. Where permanent use therefore is required, palings ought never to be adopted. But for ornament in pleasure-grounds, or for the protection of young thorns, they are highly valuable. In all cases where either dead hedges or palings are used, the decay and ultimate loss of the fence is owing to that part of it which is let into the ground being rotted by the moisture. Where dead hedges are planted it is no easy matter to provide a remedy against this evil. As the stems are so numerous, that, to give each of them a preparation that would completely defend it from the effects of moisture would be attended with an expense equal to, if not greater than, the value of the fence. Where palings, however, are used, especially the most expensive and substantial kind of them, and such as are meant both for durability and ornament, it is desirable to prepare the standards, or upright parts that are placed in the earth, in such a manner as will enable them to resist the moisture for many years. In the south of England, the post is always more bulky at the lower end than the upper and is fixed in the ground by digging a hole, placing it therein, shovelling the soil in, and ramming it round the post till it be firmly fixed. It has been a practice from time immemorial, to burn or char that part of the standards or palings intended to be set or driven into the earth. The reason assigned for this practice was, that the fire hardened the parts thus subjected to it, and, by rendering them impervious to moisture, made them more durable than they would have been without such operation. But the best defence at present known against the effects of the weather is the bark of the tree. This covering it has from nature, and is possessed of every requisite, being impregnated with oil, resin, and other matters, which secure it completely, not only against moisture, but other injuries arising from the operation of air, light, heat, &c. of this we have strong proofs by observing what happens where, by cutting off a branch or otherwise, the bark of any tree is destroyed. If the surface laid bare by the wound is considerable, that part of the body exposed by it begins immediately to decay, and continues to waste, unless some covering be made use of to supply the place of the bark, for that purpose nothing has yet been found so effectual as a coat either of boiled oil, or of oil-paint, which, by completely excluding both air and moisture, not only preserves the tree from rotting, but also prevents it from bleeding and wasting itself by an effusion of juices from the wound. When trees are cut down and sawn into planks, whether for palings or any other purpose, and are afterwards exposed to the weather, the same thing happens that we have mentioned as taking place with the growing tree when deprived of its bark, but in a much greater degree, as the whole surface is then without a covering. To prevent this decay, the same remedy should be applied, viz. painting the whole of the wood, or otherwise filling the pores with oil, in such a manner as to prevent the entrance of moisture. There are now coarse oil-paints sold of all colours, so cheap as to enable persons erecting palings, or

other works of wood, to paint them at a small expense. Other very good remedies are to be had at a moderate price, as the pyroligneous acid from gasworks, which, if the points of the standards that are to be driven into the earth are dipped into it while the liquor is boiling hot, will preserve them from the bad effects of moisture for a very long time. Previously to the dipping, they should be properly sharpened, and that part which is to enter the ground, or even the entire post if convenient, moderately charred or burnt. Common tar melted pitch, or gas liquor, may also be successfully employed for the purpose of defending the extremities of the upright parts of paling from moisture. Linseed and train oils may also be used with success, the great object being to fill the pores completely with some unctuous or greasy matter, or contract them by partial charring, so as to prevent the admission of moisture. The posts should be completely dry before they are dipped in any of these preparations for if they are either made of green wood, or have imbibed much moisture, or after being dipped are exposed either to the heat of the sun or to a severe frost, the moisture will become so much expanded thereby, as to burst through, and bring off the paint or other coating, whereas, when they are made of well seasoned wood, and are at the same time perfectly dry and the pitch, oil, or varnish boiling hot, it readily enters the pores, and, by filling them completely prevents the access of moisture and consequently the injurious effects produced by it.

3040. *The simple nailed paling* consists of upright posts, driven or set into the earth at certain distances, and crossed in three, four, or more places, with pieces of wood in a horizontal direction. This paling is for the most part made of coarse sawn wood without any dressing.

3041. *The jointed horizontal paling* consists of many square poles, driven or set into the earth at regular distances, through which mortices or openings are cut for the reception of the extremities of the horizontal pieces which traverse them.

3042. *The upright lath paling* is made by driving or setting a number of strong piles into the earth at regular distances, and crossing these at top and bottom with horizontal pieces of equal strength upon these last are nailed, at from six to twelve inches distance a number of square pieces of sawn wood, of the shape and size of the laths used for the roofs of tiled houses. This sort of paling when properly executed, looks very well, and, notwithstanding its apparent slightness, if well supported by props or rests at regular intervals lasts a long time. Where there are plantations of young firs in the neighbourhood, laths may be had at a trifling expense.

3043. *The horizontal paling of young firs or the windings of other young trees* may be had recourse to with advantage upon estates with extensive woods, or surrounded with belts of thriving plants the thinnings of such woods or belts being highly valuable for making palings, especially when the plantation consists chiefly of firs. The palings of young firs are of two kinds, either horizontal or upright. The horizontal resembles the jointed dressed paling already described, and the upright is similar to the lath paling.

3044. *The chain horizontal fence* is made by fixing a number of strong square piles into the earth at regular distances, in the direction in which the fence is to run each of these piles has three strong staples or iron hooks driven into it on each side, one near the top, one within eighteen inches of the bottom, and one in the middle to these staples or hooks chains are fastened and stretched horizontally, in the same manner as the pieces of wood are in a common horizontal wooden fence. When it is meant that the fence should be laid open for any temporary purpose hooks are driven into the posts in place of staples, and the chains hung upon them but where this is not wanted, the staples will be found the most secure method. In some cases the upright part of this fence, in place of wooden piles, such as have been described, consists of neat pillars of mason-work or cast iron.

3045. *The rope fence* is nearly the same as the former that is, it consists of upright posts, driven into the earth at regular distances, with holes bored through them for the passage of the ropes. In general there are three, and in some cases four courses of ropes. This can only be used for confining cattle or horses, for sheep it will be found quite incompetent for stretching across rivers, or pieces of water like the chain fence, the rope fence will be useful.

3046. *The movable warden fence, stake, or hurdle* This has hitherto been principally employed in cases where sheep or cattle are fed with turnips in the field, to separate a certain portion of their food at a time in that way hurdles are extremely useful, as the sheep or cattle, by having a given quantity of food allotted them at once, eat it clean up without any loss, which they would not do if allowed to ranged at large over the whole field. There are, however, many other purposes to which hurdles may be applied with equal advantage. In the subdivision of gentlemen's parks, in order to subject them to a course of aration, no fence is so suitable as the hurdle, which may be taken up and set down at pleasure, and in a short time. This circumstance being generally known, these fences never convey the idea of impassable barriers and, not being very common, they are never considered vulgar Were it not for their expense, they would be far preferable

to common fences, in districts that do not require shelter; because they occupy less space than hedges or walls, and do not, by attracting cattle, cause their manure to be unequally distributed; nor do they harbour birds or insects.

3047. *Ornamental wooden hurdle* (fig 478 and 479) may sometimes be formed at less expense of material than the common sort, because they admit of being made strong by working up short pieces of wood. Those which are highest (fig 478 a & b) may be made of oak, and six feet high, so as to be a fence for cattle others (fig 478 c) may be made of the common prunings and thinnings of young plantations. In general it is an improvement in the construction of hurdles to make the two sides so as to answer either as bottom or top (fig 480) by which means, if a leg is broken off, it is only necessary to turn the hurdle upside down, and we have still a perfect hurdle. For this purpose make the heads eighteen inches or two feet longer than usual, and sharpen both ends (fig 480), then the side pieces should be always double one on each side of the rail, and should shut in at their ends on the heads and the centre piece that their bearings may be equally strong and firm whichever end is even uppermost (Gard. Mag. vol. iv)

3048. *Iron hurdles* (fig 481) are found a very elegant and durable fence, though more than double the expense of wood. For park or lawn fences they are admirably adapted, but occupy rather too much capital for a commercial farmer

3049. *The willow, or wattled, fence* is made by driving a number of piles of any of the kinds of willow or poplar, about half the thickness of a man's wrist, into the earth in the direction of the fence, and at the distance of about eighteen inches from each other. They are then twisted, or bound together along the top with small twigs of willow or poplar (fig 482). This kind of fence has some advantages peculiar to itself, it not only forms a cheap and neat paling, but if it is done either about the end of autumn or early in the spring, with willows or poplars recently cut down, the upright parts or stakes will take root, grow, and send out a number of lateral branches; and, if pains are taken in the following autumn to twist and interweave these branches properly, a permanent and almost impenetrable fence may be formed in two or three years. For the enclosing of

marshy lands, or for completing any enclosure, where a part of the line in which the fence ought to run is so wet as to be unfit for the growth of thorns, or the building of a wall, the willow paling will be found an excellent contrivance, and the use of it will render many enclosures complete that could not otherwise have been formed. Sometimes stakes are used of a kind which do not take root and grow, in which case this form still makes a very neat and efficient temporary fence. (fig. 483.)

3050. The *paling of growing trees, or rails nailed to growing posts*, is made by planting beech, larch, or other trees, in the direction of the fence, at about a yard distant from each other, more or less, as may be thought necessary. These trees should be protected by a common dead paling, till they are ten or twelve feet high, when they should be cut down to six feet, and warped or bound together with willows at top and in the middle. Cutting off the tops will have the effect of making them push out a great number of lateral branches, which, if properly warped and interwoven with the upright part of the trees in the manner described for the willow fence, will both have a beautiful effect, and will at the same time form a fine fence, which in place of deep decaying, will grow stronger with time, and may with very little trouble be kept in perfect repair for a great length of time.

3051. The *upright and horizontal shingle fences* are chiefly made of fir, coarsely sawn into deals of from half an inch to an inch thick, and of different breadths according to the diameter of the trees. Pretty strong square pales are driven or set into the earth, and the deals nailed horizontally upon them, in such a manner that the under edge of the uppermost deal shall project or lap over the upper edge of the one immediately below it. The fence, when finished in this manner will have nearly the same appearance as the bottom of a boat or cutter. An upright fence is made by fixing perpendicular posts in the earth, nailing three pieces of wood horizontally and covering these with shingles placed perpendicularly. In this case the shingles are not above three inches broad, and the extremities of each are pointed at the top.

3052. The *warped paling fence* consists of pieces of wood driven into the earth, bent down in different directions and their tops fastened together. This fence resembles the *chevaux-de-frise* with only this difference that, in place of leaving the points standing up as is the case with that part of fortification, they are bent down and tied together. When made of dead wood, this fence is equally perishable with others of the same description. but when made of growing plants, it will be found very lasting.

3053. The *light open, paling fence with thorns or the branches of trees woven in* (fig. 484.),

differs from the common paling fence already described only in being warped either with thorns, or the branches of trees. When properly done, it forms at once a very complete fence, but, like all fences made with dead wood, it will be found very perishable and will require many repairs. It has, however, one advantage, viz that, when properly executed, it is proof against the

entrance of animals of any kind.

3054. *Primitive paling fences* are formed without nails or ties of any sort, by inserting the pales or stakes in the ground in different directions (fig. 485.), and by using forked or hooked stakes.

They are chiefly desirable in forest or park scenery for maintaining a particular character, and for separating horses, deer, &c. Such fences sometimes occur in Poland, Hungary &c. but in a civilised country they are to be considered more in the light of effect than of practical utility.

3055. *Park fences of iron* are the most efficient and elegant. (fig. 486 and 487.) Light cast-iron posts, with rails or round iron rods, five eighths of an inch in diameter, to the height of four feet, and, a foot higher, on the bent extremity of the posts, a chain instead of a rod (fig. 486.) are found to form a barrier against any description of the

larger quadrupeds kept in British parks, as horses, wild cattle, buffaloes, deer, &c. Painted green, or even with the paint called blue antisection (ground glass and oil chiefly), or coated over with the pyroligneous liquor from the gasworks, such fences are not obtrusive, and less liable to suggest ideas of limitation, confinement, restraint, &c. than walls or pales. Slightly characterised fences may be composed of connected hurdles (fig. 487), which are valuable and probably the cheapest of all fences in

dividing rich and extensive pastures, such as a park let out to a farmer for several years

growing. For poultry, or for excluding hares, rabbits, &c. the lower part of such fences is covered with a wire netting. (Fig. 488.)

SUMMARY 5. Wall Fences.

3056. *Wall fences* are constructed of different sorts of materials, and are of various kinds. They are for the most part good fences, though some of them, as those of the earthy kinds, are not by any means durable, and therefore should not be formed where better sorts can be used. In the construction of walls, it is essential that the stones be either taken from a quarry or consist of the largest land-stones broken in such a manner as to have a good flat surface, in order that they may bind well that they be built by masons, and well punned that they have as dry and deep a foundation as possible, in order to guard against frosts, &c.; that they be made wide at the bottom, and tapering upwards to about the breadth of ten inches, when the coping is to be applied that the coping consist of materials that cannot be readily overturned or removed, as, upon the manner in which it is finished, much of the future value and durability of the wall will be found to depend.

3057. *Dry stone walls* are of three kinds: those constructed of round stones gathered from the fields, and coped with tarves; of quarried stones, upon which some pains have been bestowed to put them into proper shape; and the Galloway dike, so denominated from its being originally used in that country.

3058. *The wall or dike made with round or land-stones*, by labourers, and covered with a coping of turf, is a very indifferent fence. In most instances it is not only very ill constructed as to shape, being of one uniform thickness from top to bottom but the stones, from their round figure, do not present a sufficient surface to each other to bind and give stability to the building. This fence has long been known and is still very common in the remote parts of the country upon estates where the first trade easy is made in the way of improvement, and where masons cannot readily be had. In such situations it has a two-fold benefit: the surface is cleared of many stones that would otherwise have presented a considerable obstacle to the cultivation, and the field is at the same time enclosed; but, though these objects are accomplished for a time, their benefit is not permanent, as the wall is perpetually tumbling down: even the cattle rubbing against it make considerable gaps in many places and in that way great trouble and expense are annually required to keep it in repair.

The best dikes of this kind are now built solid from bottom to top, and coped with stones resting upon others projecting beyond the width of the dike. (C.)

3059. *The wall in which the stones are quarried* (Fig. 490) and put together by skilful masons, broad at bottom, tapering gradually upwards, and finished at top with a substantial coping, has a very neat appearance, and has been known to last thirty or even forty years without repairs. A good foundation is highly essential in the construction of this fence, from nine to twelve inches is the smallest depth that it should be below the common surface, especially if the soil is open and porous; and the largest and heaviest stones should always be laid underneath.

3060. *The Galloway dike or wall* (Fig. 490) is principally employed for enclosing high grounds that are depastured with sheep, for the confining of which it seems well calculated. From two feet to two and a half at the bottom, it is built in a regular compact manner with dry stones, in every respect the same as a dry stone wall with a broad base, tapering gradually upwards: the building is then levelled with a course of flat stones, resembling a coping, in such a manner as that these flags or flat stones shall project two or three inches over the wall on each side. Above these flat stones is laid a course of rugged round ones, placed upon each other in a way secure enough to give stability to the building, but at the same time so open as to leave a considerable vacancy between each, by which means a free passage is afforded to the light and wind, which blows through them with a violent whistling noise. This rough open part of the building is generally raised three feet above the regular part of it, gradually tapering upwards, till it terminates in a top of about nine inches broad. Every course of the rugged stones being smaller than that immediately beneath it. Its tortuous appearance is so well calculated to prevent sheep, cattle, or other animals from surmounting it, that it is seldom indeed that any attempt is made to leap over it. The circumstance, together with the ease with which the stones are procured in most of the situations where the Galloway dike is used, renders it a valuable fence.

3061. *Stone and lime walls*, in order to be durable, should have a good foundation, deep enough to prevent them from being hurt by frosts, with a hipped lime, tapering gradually upwards. This fence, when properly executed, is next to hedges, the most durable it is, however, very expensive; and its superiority over the dry stone-wall is so trifling in point of durability, as to render the latter the more eligible, being much cheaper, and answering every purpose of a fence equally well. For the building of this wall, stones taken from the quarry are to be preferred to the common land-stones; for though a mason may be able to remedy, in some measure, the inequality of surface in land-stones, by mixing plenty of lime with them, yet experience proves that walls made with such stones, notwithstanding every care on the part of the builder are much less perfect, and last a much shorter time, than where quarried stones are employed. Thus, like every other stone fence, should be secured at the top with a substantial coping. Stone fences of every description not only form complete enclosures at once, and by that means allow the proprietor to enter into immediate possession of every advantage that can arise from the enclosing of his fields, but, by the little room they occupy a considerable portion of land is saved.

3062. In the construction of walls of stone and clay the clay is used like lime, and is meant to answer the same purpose. It requires slender observation to convince intelligent persons, that a wall made with such materials in the ordinary way cannot be a durable one; for if the clay made use of in building the fence has been very moist, the summer's heat will dry it so much as to leave considerable chasms in the building; these chasms must necessarily deprive many of the stones of that support which they require, and in that way endanger the building. This, however is not the only inconvenience with which this kind of wall is attended; the effect of the summer's sun upon the clay particles is so completely that when the wet weather comes on about the end of autumn it absorbs the moisture like a sponge, and if it is overtaken by frost while in that state, the fabric swells, bursts, and tumbles down.

3063. *Walls of stone and clay, dashed with lime*, differ in no respect from that described, except in the harling or dashing that is given them. Where that operation is well performed, and at a proper season of the year, the coating of lime, by preventing the entrance of moisture, will add greatly to the durability as well as beauty of the wall; so much so, indeed, that some fences made in this way, where the clay was properly tempered, and did not contain too much moisture, and where a harling or dashing of lime was afterwards given, have been known to last nearly as long as walls made entirely with stone and lime.

3064. *The dry stone wall, hipped with lime*, differs from the ordinary dry stone wall, in having about two or three inches of it on each side hipped with lime, which gives it the appearance of being built entirely with stone and lime. Where the external appearance of a fence is an object, something is gained by this practice; in point of real duration however it seems to possess very little advantage over the common dry stone-wall which, when properly executed, lasts equally long.

3065. *Dry stone walls hipped and harled*, are much the same, nothing more being added than a harling or dashing of lime after the other work is finished. This addition is to be considered merely as an improvement upon their appearance and not as contributing to increase their utility or render them more durable as fences.

3066. *Dry stone walls pinned and harled*, are much the same the mason only carefully pins or fills up all the interstices of the building with small stones, after they have been built in the ordinary way, and afterwards dashes or harls them over with lime. The pinning by filling up every vacant space, and affording complete support to the stones in every part of the surface, adds considerably to the durability of the building, and the harling afterwards gives the whole a finished substantial appearance which renders them at once agreeable to the eye, and lasting as fences.

3067. *The dry stone wall, with a light paling upon the top* is sometimes made, and for particular purposes answers well, and has a handsome appearance when well executed.

3068. *Brick walls* are seldom had recourse to for ordinary enclosures, except in situations where stones are extremely scarce (as is the case in some countries), and for pleasure-grounds, and for park or garden walls. In Nottinghamshire we have observed brick walls of open work, in the manner of the walls of Mac-Phail's dungeons but the same brick wall we should think preferable as a field wall. (See *Enc. of Gard. and Gard. Mag.* vol. v. p. 878.)

3069. *Frame walls* are constructed in the following manner — A frame of deal boards, of a width and height proportioned to that of the intended fence, is placed upon the line in which it is intended to be made, a proper foundation having been previously dug the frame is then filled with stones of all sorts, gathered principally from the adjoining fields when the frame is filled to the top with such stones, a quantity of liquid mortar is poured in amongst them, sufficient to fill up every interstice the whole is suffered to remain in that state till it is supposed that the mortar has acquired a suitable degree of firmness to give stability to the building, which in summer, when the weather is warm and dry, will not require above a day or two. The frame is then removed, and placed a little farther on in the same line, in such a manner as that one end of it shall join immediately with that part of the work from which it had been removed. In this way the line of fence is gradually completed, which, when the lime is of good quality and well mixed with sharp sand, and the proper pains taken to incorporate it with the stones, presents a smooth uniform surface, and will doubtless form a substantial and durable fence.

3070. *Turf walls* are met with in almost every upland or hilly district throughout Britain, and for temporary purposes are found very useful. In a variety of instances this sort of fence is used for enclosing fields, and is practised for that purpose to a very considerable extent; in others, however it is used for the formation of folds, pens, or other places of confinement for cattle during the night. In general, the fence is made with turf only, pared off from the adjoining surface, and used without any mixture of earth in other cases, the wall consists of a facing of turf on each side, while the space between is filled up with loose earth. For a fold, this fence answers extremely well; but for enclosing a field, or indeed any other purpose where durability is required, it

should never be used, as from the moment it is finished its decay commences, and no pains or attention will be able to keep it in repair after it has stood two or three years.

3071. *Stone and turf walls* are also very common in many situations, where better and more durable ones could be made at equal, perhaps less, expense. In many instances, however, they are employed from necessity where lime is either very dear, or not obtainable at any price.

3072. *Mud walls*, with a mixture of straw, were formerly frequent in many places, not only for surrounding small enclosures and duck-yards, but also for the walls of barns, houses and offices, and for subdividing houses into different apartments. When either the outside walls, or the inside divisions of a house are to be made of these materials, the custom is, to take a small quantity of straw and incorporate it with a sufficient proportion of clay: the straw in this case answers the same purpose as hair in lime-plaster. When a sufficient number of small masses are made, the work is begun by laying a stratum at the bottom of the intended wall, this being done, and the different pieces firmly knined or worked together with the hand, a flat deal board is applied on each side, which, being properly pressed and rubbed against the building in a horizontal direction, not only serves to consolidate the work, but gives it a degree of smoothness and uniformity. Successive strata are added, till the wall is raised to the intended height, care being taken to taper it gradually upwards. Walls made in this way, if properly constructed will last for many years; and, if dashed or harled with lime at a proper season of the year, will have an appearance no way inferior to such as are made with stone and lime; along with this addition to their appearance, the harling or dashing with lime, if properly done, will, by preventing the access of moisture, render them much more durable.

3073. *Rammed earth or an pieh walls* are very common in France, both as fences and walls for buildings. They have been described at great length in the *Chémennations to the Board of Agriculture*, and in other works, and tried in various parts of this country with tolerable success, though they are by no means suited either to our moist climate, or degree of civilisation. In constructing them the earth is previously pounded, in order to crumble any stones therein: clay is added in a small quantity, about one eighth part. It is all beaten and mixed up together by repeated blows with a mallet about ten inches broad, ten or fifteen inches long, and two inches thick. The earth being thus prepared, and slightly wetted, the foundation of the wall is dug. This is laid with stone and, when it is about one foot high above the surface of the ground, planks are arranged on each side, and the space between filled with the earth intended for the wall, which is strongly beaten. This method is continued successively till the wall is completed.

3074. *Stamped earth walls* are the invention of François Couteraux. Earth prepared in the same manner as for rammed walls, is put into a mould or box of any size, generally that of the proposed wall's thickness in width, one or two feet long, and about one foot high. (Fig. 491. a) The mould is a strong cask or iron box, and the earth being placed in it, is compressed either by the action of a press acted on by a lever or screw or a stamping-engine similar to the pile-driver or great forge-hammer. The stone, or solid body of earth (b) thus acquired, is then used in the same way as common hewn stone, and either bedded or merely jointed with lime-mortar; it is then washed or harled, both for effect and duration. Various machines for forming bricks and stones for the ordinary purposes of building fence walls, and sheds, and other buildings of one story high, may be found in the eighth and ninth volumes of the *Mechanic's Magazine*.

## CHAP. V

### Gates and Bridges appropriate to Agriculture

\*3075. The gate may be considered as a movable part of a fence, or as a frame of timber, or iron, readily moved, and calculated to give a convenient inlet and outlet to enclosures. Gates may be considered in regard to the principles of their construction and fixing: the materials of which they are made, and their different kinds.

3076. With respect to construction, the great object is to combine strength with lightness. The absolute strength of materials depends on their hardness and tenacity. A gate, therefore, consisting of one solid plate of wood or iron, would seem to require most force to break or tear it in pieces: but this would not be consistent with lightness and economy, and in the use of such a gate it would be found to open and shut with more difficulty than one less strong. The skeleton of a plate of wood or iron is, therefore, resorted to by the employment of slaps or bars, disposed and joined together on mechanical principles. These principles, applied to carpentry, direct the use of what are called ties and struts, in the judicious composition of which, as far as construction is concerned, consists the whole art of carpentry. A tie (Fig. 492. a) is a bar, or piece of timber, so placed in a structure as to resist a drawing or twisting power; a strut (b) is one so placed as to resist weight, or whatever has a tendency to press or crush. The horizontal bars of

a gate are all ties; the diagonal and perpendicular ones struts. On the judicious combination of these ties and struts depends the absolute strength of the gate and on their lightness, and on the general form of the gate, depends its adaptation for opening and shutting by means of hinges.

3077 The construction of a gate best adapted for opening and shutting is next to be considered. All gates, after being hung, have from their gravitation a tendency to deviate from their original position, to sink at the head or falling post, and thus no longer to open and shut freely. If the construction and hanging of the gate were perfect, this could not possibly take place but as the least degree of laxity in trussing the gate, or want of firmness in fixing the post in the ground, will occasion, after frequent use, a sensible depression at the head, it becomes requisite either to guard against it as much as possible in the first construction, or to have a provision in the design of the upper hinge (fig 493.) for rectifying the deviations as they take place.

3078 In order to understand the construction best calculated to resist depression, suppose a gate hung and resting on its head (fig 492.c) acting as a strut, and maintained thereby its upper hinge (d) acting as a tie, then the bottom rail of the gate considered as representing the whole, becomes a lever of the second kind, in which the prop is at one end (c) the power at the other (g) and the weight placed between them in the line of the centre of gravity of the gate (b). Now as two equal forces, to hold each other in equilibrium, must act in the same direction it follows that the power acting at the end of the lever (g) will have most influence when exerted at right angles to it in the line (g e) but as this cannot be accomplished in a gate where the power must be applied obliquely it follows, that a large angle becomes requisite that the greater the angle, the greater the power or in other words, the less the strain on the construction of the gate or the less the tendency to sink at the head.

492

five proportions will still be the same, and the advantages and disadvantages will be rendered more obvious.

3079 Waistell and Parker have paid great attention to the construction of gates for many years. More than fifty years ago, Waistell circulated among his friends plans for ornamental gates with semi-oval and semicircular braces, and such gates (fig 496) have now become general. Parker has directed his principal attention to the hangings and fastenings of gates and his forms of latches hinges, &c. as well as his turnpike-gates (fig 495), are also very general.

3080 The construction of the gate is thus given by Waistell. The head (fig 493. a) and head (b) are to

be formed of oak, and the bars and braces of foreign fir. If inferior materials are used, they may be made a little thicker but the breadth should remain the same.

	A	B	by inches
The head of the gate to be about	5 1/2	5 1/2	28
The head of stile	2 1/2	2 1/2	14
The top rail, or bar vertical place	2 1/2	2 1/2	14
ditto horizontal place	2 1/2	2 1/2	14
The bottom bar	2 1/2	2 1/2	14
The other four bars, and the four braces	2 1/2	2 1/2	14

The dimensions in column under A are taken on the face of the gate those in the column under B are taken in the direction of its thickness. Narrow and thick bars, when braced as in this design, are stronger than broad and thin ones, containing the same quantity of timber and they also oppose a less surface to the

would be at its highest elevation, and would have a tendency to fall either way until it arrives at A when the head will be at its lowest descent. If the gate be shut, the spear and catch prevent the head from falling to its lowest position; but the tendency it has to fall to A is designed to assist in keeping the gate closed. The iron-work of the gate ought at least to be painted. If the whole of the gate be painted, the appearance is greatly improved; and if, when painted, the wood be quite dry, it will be likely to last longer. Gates, in close situations under trees, although painted, will sooner decay than gates not painted in open and more exposed grounds: and this circumstance has, perhaps, induced some persons to conclude that the paint, instead of the situation under trees, was injurious to the gates.

3083. *Further a compensation hinge, for gates which are much in use (fig. 495.) is an excellent corrective*

to their falling; all that is necessary when the gate sinks at the head, is to screw it up by the nut (a) till it regains its original position. For road and farm yard gates the hinges are valuable parts of the construction.

3083. *A gate should be so hung as to have two joints; one to the hanging-post, to make it catch,*

and the other to a point at right angle with the gateway as to keep it fully open. To effect this purpose, having set the post perpendicular let a plumb-line be drawn upon it; on this line, at a proper height, place the hook so that it may project three inches and a half from the face of the post and at a convenient distance below this place the lower hook an inch and a half to one side of the perpendicular line, and projecting two inches from the face of the post; then place the top loop or eye two inches from the face of the hanging style, and the bottom loop three inches and a half. Thus hung the gate will have a tendency to shut in every position. A gate so hung will have a tendency to shut in every position because if the weight of the gate be represented by a diagonal line from the head to the heel, thus, by the resolution of forces, is resolvable into other two lines, one perpendicular, and the other horizontal: the former representing that part of the weight which presses in a perpendicular position, and the latter that part of the weight which presses in a horizontal direction and gives the gate a tendency to shut. (Northumb. Rep. 63.)

3084. *Gates are generally constructed of timber* and whatever kind may be used it is essential that it be well seasoned, as, without attention in this respect, they are soon decayed in their structure by the heat of the sun they should also be well and correctly put together. Oak is undoubtedly the best sort of wood for the purpose, where durability is the object though some of the lighter kinds of woods, as deal, willow, &c. will often last a great length of time, as, from their lightness, they are not so apt to destroy themselves. The lighter gates are made towards the head or opening part the better, provided they are sufficiently strong for the purpose they are to serve and on this account the top bars may, in many cases, as where horses are to be kept, be left considerably stronger than the others. If this is not done, they are liable to be broken by the animals rubbing their necks upon them, except where they are made very high. Gates are generally made eight and a half or nine feet in width, and from five to six feet in height, the bars being three or four feet broad, and five or six in number. In particular instances a smaller bar is introduced between the two lower ones, in order to prevent small animals getting through.

3085. *Iron, both hammered and cast metal, has long been in use for ornamental gates (fig. 496.), and has lately come into use in some districts for field gates.* Their eligibility

must depend on their price and durability with relation to wood. At the ordinary prices of wrought iron and oak, they will be found of doubtful economy, cast-iron gates are too heavy, and too liable to be broken, for agricultural purposes.

3086. *The posts or pillars to which gates are attached should, in all convenient cases, be formed of stone; as this material, when hewn and properly constructed, will last for ages. When formed of wood, oak and larch are the best sorts. The latter, where suit-*

also, should be used without removing the bark, which has been found to add greatly to their durability. In some places it is customary to plant trees for gate-posts, and after they have attained a certain size and thickness, to cut them over about ten feet above the surface where the trees thrive, they form the most durable of all gate-posts; in many instances, however, they fall, and much trouble is necessary to repair the defect. Where the posts are made of *dead timber* they should always be strong, and the wood well prepared: that part which is let into the earth should also be defended, by dipping it in coarse oil, or giving it a coat of pyroligneous liquor, and all that is above ground exposed to the action of the weather, should be well covered with one or two good coats of oil-paint. The expense of this preparation is but trifling, while the benefit is very great.

3087. The substance of a gate-post, according to Parker should be from eight to ten inches square, or for very heavy gates a foot square would not be too large. If made of still larger size, it is better. The steadiness of a gate-post, he says, depends in a great measure upon the depth to which it is set in the ground, which ought to be nearly equal to its height. Five or six feet are, in general, fully sufficient but the posts may be kept in their places by a strong frame-work placed under the ground, extending between the posts.

3088. The fastenings of gates, it is observed by Parker (*Essay*, &c. 1816.), are as various as the blacksmiths who construct them. The subject occupied his attention in connection with the hanging of gates, and he has introduced various improved forms. One of the most secure (Fig. 497) is a spring-latch (a), opened by a lever (b) which works in a groove in the upper bar of the gate, and therefore cannot be rubbed open by cattle, while, by means of a knob at the end of the lever, and rising up against the top of the upright bar (c), so that cattle cannot touch it, it is very easily opened by persons on horseback with or without a stick or whip.

3089. A simple, economical, and effective spring-latch consists of a bolt (Fig. 498 a.) which is loose, and plays freely in two morticed openings in the upright bars, and is kept in place by a spring (b).

The gate may be shut from either side, when the bar, striking against the projection (c) on the sliding-post, is pushed back till, arriving at the mortice (d), the spring (b) forces it in and the gate is shut securely. Such a gate is easily opened by a rider. This is a good latch for the common field gates of a farm.

3090. For gates of an ornamental kind, Parker says, he does not know a better latch than the crooked lever (Fig. 499) now in common use.

3091. The reversed latch (Fig. 500) is one of the latest improvements in this department, and is particularly suitable for the gates in a gentleman's park. On the edge of the head of the gate a pin (a) is screwed; and on the sliding post a plate containing two latches (b c) turning on pivots. Whichever way the gate is opened, it is left to shut itself or it shut by force, it easily passes within the one latch and is retained between that and the other. Taking it altogether this is one of the cheapest and best field-gate latches. Where a gate may be made of one half the size, and with only one of the latches, according to the side on which the gate opens.

A contrivance of this sort is in use at some of the pleasure-ground gates at Brompton Hall, near Barnsey Yorkshire, and is found very efficacious and satisfactory. There are also some very handsome iron gates at that residence, which with the latch stopper alluded to, will be found figured and described in the *Gardener's Magazine*, vols. vi. and vii.

3092. Gates are of different kinds (Figs. 501 and 502.), according to the particular custom of the district but the principal sorts made use of are, the swing gate, the folding gate, the slip-bar gate, and the wicket and turn about gate.

3093. The improved swing gate of the northern counties is well adapted for agricultural purposes. There is a projection on the lower part of the hanging stile, which, when the gate is closed, there is also a diagonal bar through which the stile passes upwards, and the principle of operation are well understood among the country carpenters and hedges of these parts.

It is found to be a very strong and durable gate, and its construction, hanging, and principle of operation are well understood among the country carpenters and hedges of these parts.

503. In *Farmer's improved swing gate*, the diagonal bar rising from the lower part of the head of the gate meets the middle of the rail, and the two upright bars are placed at proper distances between the

spring and the head of the gate; these cross bars must, he thinks, assist very much in keeping the gate together; but what is most to be guarded against is its shutting the head, to prevent which this gate is, he says, well contrived.

504. *Monteant's fold-gate* (fig. 504) is a very light and strong form, and at the same time not expensive. When the head sinks, it is raised by the simple operation of applying a larger wedge between the key wedge, which raises the hook of the upper part of the head (a), and the hanging-post. The fastening latch is

protected from the rubbing of cattle by a recess in the falling post (b). Gates of this description are

generally made in Scotland of pine or fir timber or what is called foreign plank or deal. Mr. Monteant has the good fortune to possess on his own estates extensive plantations of pine planted by himself, and already affording an ample supply for gates and other purposes. We have already adverted to his mode of raising the timber more durable by steeping it in lime-water: the same process will also render it less liable to warp when applied to the construction of gates. In England, when gates are to be painted or tarred, they are generally made of pine or fir when not to be painted, of oak.

505. *Inventor of Thurston's economical fold-gate* (fig. 505) is said to be very light and durable. The hanging-post is held in its place by one or two coarse props of wood (a) and when it can be got, by a large stone (b). The inventor gives the following

**Description and**

"With the exception of a small spar for lambs, all parts of the above gate taper regularly from four inches to three inches in breadth and from one and a quarter to three quarters in thickness but any other proportions may be adopted.

It is not placed between the posts, but on the face of the hanging post.

"The hinges are not near any joinings of the wood.

"Each part of the under hinge is one inch and a half longer than the upper and the upper shortens by means of a screw and nut.

"The gate is divided into four parts, of which the diagonal enhances two.

**Advantages.**

"This makes the gate as light as possible, without diminishing its strength and, by bending, it will save the risk of breaking like the reed in the gale.

"This causes it to fall back on the ledge when open, so that a cart cannot strike it.

"This gate will not rot at the hinges.

"It will either open or shut of itself, except when three quarters open and, if the punt should droop, the upper hinge will take it up and it prevents the joining of the upper bar at the head of the heel (c) from separating.

"The gate being ten feet by four this is probably the best angle for a diagonal, and it hardly requires a nail to keep it in its place." (*Quart. Journ. Agr. vol. u.*)

507. The improved park-gate (fig. 505.) deserves to be more generally adopted, particularly in the fields near gentlemen's houses where there is much inter course. Much of the excellence of this gate depends on the manner in which it is hung, and the following improved mode of hanging is given in the *Quarterly Journal of Agriculture*.

"The upper hinge (a) fixed on the topmost bar of the gate, is formed with a band or crook in the common manner and is received into the socket of the hinge (b) which may either be fixed in the post by lead, or continued through it, and fixed with a screw nut. The advantages of forming the upper hinge to move in a socket are 1. That, while space is given it to play it is firmly supported in its place. 2. That the means are afforded of causing it to move smoothly at all times, by pouring a little oil into the socket. The lower hinge is formed on the principle of affixing two pivots, or points of support, to the lower part of the gate. It consists of two iron plates, placed horizontally at the distance from each other of three eighths of an inch the upper of which (d) is fixed to the post, and the lower (c) to the gate. From the underside of the upper plate project two cylindrical knobs of iron, placed perpendicularly. These are received into the upper plate c, so that the gate rests upon the two upright pieces of iron as pivots. The gate, when shut, has thus three distinct points of support, namely the socket of the upper hinge, and the two lower pivots, the former of which is thus placed at the vertex, and the latter at the base of an isosceles triangle. From this construction, it results that the gate is only in a state of equilibrium when, being shut, it rests on both the lower pivots, and that, when opened, it must tend to regain its former position. The more distant from the lower points of support the socket is placed, the more firmly is the gate retained in its place, and prevented from trailing on the ground; and the more distant from each other these two points are, the more strongly does the gate

tend to keep the perpendicular position in which alone it is in a state of equilibrium. The upper hinge should, therefore, be placed on the highest bar of the gate. The distance between the centres of the two cylindrical limits of iron (m & n) may be 5 inches, which will be found sufficient to give a strong impetus to the gate to shut itself. The power of a gate to shut itself in all cases, is a certain advantage, even where fields are in a course of constant cultivation, and a very obvious advantage where they are kept stubble in grass. There is no providing, in ordinary cases, against the carelessness of persons, who will rather leave a gate open than undergo the little labour required to shut it. There is an apparent objection, indeed, to this species of gate, which is, that each time a cart or wagon passes, the gate must not only be opened, but held open until the carriage has passed. The inconvenience, however, from this is not so great in practice as might be supposed. It is very rare that farm horses will not obey the voice of the driver, and pass while he holds the gate open with his hand. Where the gate must be kept constantly open, as when there is a landing of corn or hay from the field, or of manure to  $\frac{1}{4}$ , it can either be propped back by a stone, or removed from the hinges, and laid aside till wanted; or all inconvenience of this nature may be avoided effectually by sinking a stone in the ground, and fixing to it a simple hook or latch, to which the gate may be attached when opened.

**500.** "The lock of a gate of this kind must be made to open with as little force as possible. To this end, the spring (q), two feet in length, is fixed nearly at right angles to the piece of iron (f), which passes through the head of the gate, and is attached to the handle by a joint or hinge fixed to the handle (g) while the handle itself is attached to the back of the head by a similar joint. The notch in the horizontal plate, for the reception of the spring, must be in the plane of a perpendicular from the upper hinge."

**501.** The dimensions of this gate are as follow:—"There are two horizontal one diagonal, and four upright bars. The broadest of the latter or, as it is generally called, the head, is 4 inches by 5, and the foremost, or head, 3 inches square. Into these are morticed the extremities of the horizontal bars. The uprights, or braces, consist of pieces of plank nailed to one side of the gate, 5 inches by 14. The diagonal, from the lower end of the head to the upper end of the head, is of the same dimensions, and is nailed to the opposite side of the gate. The head rises a foot above the upper bar, the other uprights 6 inches above it, and all of them project about 4 inches below the lower bar, which again is 6 inches from the ground. The horizontal bars taper from the head to the head, being 8 1/2 inches square at their junction with the former, and 3 1/2 inches at their junction with the latter. They may be revolved a little at top. The length of the gate, including the breadth of the head and head, is 6 feet, the height over the head 5 feet 9 inches; the distance between the head and the pillar 5 inches and between the head and the pillar 5 inches. The plate for receiving the spring of the latch is 11 inches in horizontal breadth."

**502.** The best species of post or pillar "is a single stone of granite, greenstone, or any of the hardest rocks. In this case, instead of fixing the bands of the hinges into the stone, by running them in with lead, they should be carried through to the opposite side, and fixed by a bolt or screw nut. When wood is used for the post, any common kind, whether fir or hard wood, which is unfit for other purposes, may be employed. For the gate itself, the best material timber only should be used. Spruce is liable to break, and larch to warp, and Scotch pine, it is well known, when exposed to the weather is one of the least durable of the pine tribe. All the mortises of the gate, and the parts at which the uprights and diagonal cross the bars, should be carefully coated with white lead, and when the parts of the gate are joined together the whole should afterwards receive two coats of paint. Gates of limbed wood, constructed on these principles, and with these precautions, have been known to last for thirty years, without repair or tending to fail upon the ground. Expense in all 21 7s." (*Quar Jour Agr* vol. I. p. 727.)

ing and shutting, which, when servants or others are passing through it in a hurry occasions its being frequently left open. In other respects, it is preferable to every other description of gate, both in the original cost, and greater durability. It is to be noticed, however, that upon the verge of a farm or estate, especially where it is bounded by a high road, the slip-bar gate will not answer as it does not admit of being locked or secured in the same way as other gates but in the interior of a farm or estate, it will be found the cheapest sort of gate.

**503.** The cheapest slip-bar gate, though more expensive, is not liable to the same objections as the last. Here the bars are connected by a chain down the middle of the gate, and therefore, if one bar is padlocked to the post, none of them can be moved till that one is unlocked.

**504.** The turn-about, or wheel-gate, is only used in cases where there is a necessity for leaving an entry for the people employed to pass backwards and forwards. This purpose it answers very well, and at the same time keeps the field completely enclosed, as it requires no trouble to shut it in the time of passing.

**505.** The double, or folding gate (Fig. 507) is considered by some to be much more durable than those of the swing kind; because the bars, from being only half the length, render the joints of the gate not so liable to be broken, or the hinges to be hurt by straining. On the other hand, such gates require more time and attention in the opening and shutting, and the latter operation is troublesome to perform, when both halves have fallen at the head. These gates are not, therefore, in such general use in agriculture as the swing kind, but they are common to gates to parks, and other scenes of dignity and ornament.

**506.** Clark's window-seat gate (Fig. 508) is a recent invention, which may be of use in some cases, especially in farm-yards. It is suspended by two weights, and shuts exactly on the principle of the window-seat. The weights may be of stone or cast iron, and the pulleys are of iron and nine inches in diameter. It was applied in the first instance to a cattle-court, but has since been erected in different situations. Its advantages the inventor considers to be the following:—It is easy to open (b), or shut (c) remains in whatever situation it is placed; is not liable to be beaten to pieces by the action of the wind; shuts always perfectly close, whatever be the height of the straw or dung in the court or gateway; a cart may be driven quite close on either side before opening; is perfectly out of the way when fully open, and not liable to shut on what is passing; the gate bottom not liable to decay by being immersed in the dung, as is commonly the case with cattle-court gates; not liable to go out of order; may be erected in a hollow place, where a swinging gate could not open either outwardly or inwardly; and is likely to be more durable than ordinary gates. A small gate of this description (Fig. 508) is said, by *Lancashire (Nat. de Machines, &c.)* to have been long in use by the Dutch.

507. *Parker's sympathetic park-gate* (Fig. 510.) is an ingenious contrivance, by which on the approach of a carriage, the gate opens apparently by its own volition, and closes again after the carriage has passed through, without any apparent cause. The manner in which this extraordinary effect is intended to be produced is, by small plates let into the ground at short distances from the gate, and when the carriage wheels roll over them, they are made to descend like a weighing machine, and to act upon certain levers concealed

in a trunk under the road, by means of which a toothed wheel is made to revolve, and to turn a toothed pinion affixed to the swinging-post or axle of the gate, and hence to throw it open or close it. (*Newcomen's Journal*, vol. xiv p. 232.) In an agricultural point of view this gate is of no use, but as a curiosity it is worth noticing, and perhaps in the drives or ridings in some pleasure-grounds and parks it might be worth executing. In England it might save the tax on a groom, and in America and Australia it might be as good as a helper which, for such aids as opening gates are not very easy to be found.

5108. *Stiles* are contrivances for men to pass over or through fences, without the risk of even permitting the larger quadrupeds to accompany or follow him. There are many forms perfectly well known every where as by steps over a wall, by a zig-zag passage, formed by stakes, through a hedge or paling a turning-bar or turnstile, &c.

5109. *The stile of falling bars* (Fig. 511) is chiefly used in pleasure-grounds, or between paddocks

it consists of bars, light at one end (a) and heavy at the other (b), with concealed joints or pivots, in an upright post (c) placed nearer one end of the bars than the other. Then, while the weight of the short end of the bars keeps them in a sensible position, a slight pressure on the other end will form a passage (d) which any one may easily step across.

5110. *Bridges* are frequently required on estates and farms, for crossing ditches and water-courses. They are generally large stone conduits or barrel-drains; or in the case

of large streams, arches of masonry. In the case of small drains, wooden pipes or boarded tubes are sometimes resorted to, and even earthen pipes have been used; but masonry should generally have the preference.

## BOOK V.

### OF THE OPERATIONS OF AGRICULTURE.

3111 *The operations of agriculture are effected under the direction of man, and by means of the mechanical agents, or implements and buildings, which have passed in review in the preceding book. They are either performed directly on plants or animals, which may be considered the objects of agriculture, or on the soil and climate, which are the natural agents of growth and culture. They may be arranged as manual labours and operations, operations with beasts of labour, and mixed operations.*

#### CHAP. I.

##### *Manual Labours and Operations.*

3112 *The labours and operations of any art can seldom be described with great advantage. Whoever wishes to acquire them should resort at once to the scene of action: no description, however minute, will teach a man to dig, plough, or mow, equal to a few hours' trial in the field, though a knowledge of the mechanical principles on which the implements and the human machine act in such operations, will afford some assistance in acquiring them, and in performing them with ease. Our observations shall chiefly be directed to these parts of the subject, and to the most suitable weather and other circumstances for the performance of the different field labours of the manual kind. We shall arrange these as manual labours common to all arts, manual operations on the soil, and mixed manual operations, or such as are performed on the soil, plants, and animals, together or connectedly.*

##### *SECT. I. Mechanical Operations common to all Arts of Manual Labour.*

3113 *All the operations which man performs with implements or machines are, as far as his own person is concerned, reducible to lifting, carrying, drawing, and thrusting. Man himself considered as an engine, derives his power from alteration in the position of the centre of gravity, and he applies it chiefly by his hands, arms, and legs acting as levers of the third kind.*

3114 *Lifting is performed by first stooping, or lowering the centre of gravity, and at the same time throwing it to one side. The object being then laid hold of by the hands, the body is raised, and the centre of gravity in being restored to its true position, acts as a counterbalancing weight to the weight to be raised. The weight retained by the hand is now raised a certain height, never exceeding half that of the man. If to be raised higher, recourse is had to muscular strength, or the power of the arms to act as levers.*

3115 *Carrying. To carry a thing is merely to walk with a greater weight than before, and walking is performed by a series of alternate derangements and adjustments of the centre of gravity slow or rapid, as the person may walk or run. According to DeLolme, the most advantageous weight for a man of common size to carry horizontally is 118 lbs. or, if he returns unladen, 135 lbs.*

3116 *Drawing. In this operation, the upper part of the body is thrown forward, so as to act as a power to counterbalance or lift up the body or weight to be moved, and joining to this lifting motion the operation of walking, the weight is at once lifted up and drawn along. This compound operation is exemplified in a horse, when straining a draught in a plough or cart: he first lowers his chest, then raises it, and lastly steps forward. When drawing at ease, the lifting motion is scarcely distinguishable from the progressive one.*

3117 *Pushing, or thrusting, is performed exactly on the same principles as drawing, and differs from it chiefly in the kind of implement or machine which requires to be employed. All machines which are to be pushed requiring to be attached to the animal machine by parts acting by their rigidity, whereas those to be drawn may be attached by parts acting by their tenacity merely.*

3118 *Wheeling is a mode of carrying materials in which the weight is divided between the axle of the wheel and the arms of the operator. The arms or shafts of the barrow thus become levers of the second kind, in which the power is at one end, the fulcrum*

at the other, and the weight between them. The weight is carried or moved on by the continual change of the fulcrum with the turning of the wheel; and this turning is produced by the operator throwing forward his centre of gravity so as to push against the wheel by means of the movable axle, &c. The chief obstacles to wheeling are the roughness or softness of the surface to be wheeled on. Where this is firm, there wheeling will be best performed with the greater part of the load resting on the axle but where soft and deep, the centre of gravity should be nearest the operator who will find it easier to carry than to overcome excessive friction. Dry weather is obviously preferable for this operation. "With wheelbarrows," Dr Young observes, "men will do half as much more work as with hods."

§119 *All these operations may be varied in quantity, either by a variation in the weight or gravity of the man, or moving power or by a variation in the time or rapidity of his motions.* Thus a heavy man may, in one movement, lift a weight ten times greater than can be done by one of less weight; but a light man may, by increasing the time of performance, lift the same weight at ten times. A man, who in digging can apply with his feet five cwt. of his weight towards pushing the wedge or blade of the spade into the soil, has an apparent advantage over a lighter man who can only apply three cwt. of mere gravity for that purpose but yet the latter may equal the former, by accompanying his power, or foot, with a proportionate increase of motion. The power in this last case is said to be obtained by the momentum, or quantity of matter in a body multiplied by the velocity with which it is moved. Power therefore, we thus ascertain, is obtained by matter and motion jointly and what may be deficient in the one, may be made up by excess in the other. Thus, a small light workman may (though with more animal exertion) produce as much work as a larger or heavier man for if we suppose the quantity of matter in the large man to be thirty, and his motion at the rate of two, then if the quantity of matter in the small man be twenty, and his motion at the rate of three he will produce an equal effect with the large man. As small human machines, or men are generally constructed of finer materials, or more healthy and animated, than large ones, the small man performs his rapid motions with nearly as great ease to himself as the heavy man moves his ponderous weight, so that in point of final result they are very nearly on a par

#### SECT II *Agricultural Labours of the simplest Kind.*

§120. *The manual labours of the field are, next to the general labours enumerated, among the simplest required of the human operator, demanding, in addition to health and strength, but little skill in their performance.*

§121 *Breaking stones is an easy labour requiring very little skill and no great degree of strength. The stones are previously reduced in the quarrying, or otherwise, to sizes at which they can be broken by one blow or more of an iron-headed hammer. In general they are broken on the plane on which the operator stands, but the blow has more effect when the stone is raised about eighteen inches and, for small stones, the most work will be done when they are broken on a table nearly as high as a man's middle, which is now the practice under the direction of the best road-makers.*

§122. *Picking. The pick is a blunt wedge, with a lever attached to it nearly at right angles and the operation of picking consists in driving in the wedge so as to produce fracture, and then causing it to operate as a compound lever by the first lever or handle, so as to effect separation, and thus break up and loosen hard, compact, or stony soils. It is also used to loosen stones or roots and the pick-axe is used to cut the latter. For breaking and pulverising the soil, the most favourable conditions are, that the earth should be moderately moist, to facilitate the entrance of the pick, but in tenacious soils not so much so as to impede fracture and separation.*

§123. *Digging. The spade is a thin wedge, with a lever attached in the same plane, and the operation of digging consists in thrusting in the wedge by the momentum (or weight and motion) of the operator which effects fracture a movement of the lever or handle next effects separation, whilst the operator, by stooping and rising again, lifts up the spiltful or section of earth on the blade or wedge of the spade, which, when so raised, is dropped in a reversed position, and at a short distance from the unbroken ground. The separation between the dug and undug ground is called the trench or furrow; and when a piece of ground is to be dug, a furrow is first opened at that end of it where the work is to commence, and the earth carried to that end where it is to terminate, where it serves to close the furrow. In digging, regard must be had to maintain a uniform depth throughout to reverse the position of each spiltful so that what was before surface may now be buried, to break and comminute every part, where pulverisation is the leading object; to preserve each spiltful as entire as possible, and place it separated or isolated as much as can be effected, where saron is the object to mix in manures regularly, where they are added, to bury weeds not likely to rise again, and to remove others, and all extraneous matters, as stones, &c., in*

every case. For all these purposes a deep open trench is requisite; and, that this may not be diminished in width and depth in the course of the operation, it must never be increased in length. If allowed to become crooked by irregular advances in the digging, it is thus increased in length, and necessarily diminished in capacity, unless, indeed, the dug ground is allowed to assume an uneven surface, which is an equally great fault. Digging for pulverization, and mixing in manures, is best performed in dry weather; but for the purposes of aeration, a degree of moisture and tenacity in the soil is more favourable for laying it up in lumps or entire pieces. The usual length of the blade of the spade is from ten inches to a foot, but as it is always inserted somewhat obliquely, the depth of pulverization attained by simple digging seldom exceeds nine inches, and in breaking up firm grounds it is seldom so much.

5124. *Shovelling* is merely the lifting part of digging, and the shovel, being broader than the spade, is used to lift up fragments separated by that implement or the pick.

5125. *Marking with the line* is an operation preparatory to some others, and consists in stretching and fixing the line or cord along the surface, by means of its attached pins or stakes, in the direction or position desired, and cutting a slight continuous notch, mark, or slit, in the ground, along its edge, with the spade.

5126. *Trenching* is a mode of pulverizing and mixing the soil, or of pulverizing and changing its surface, to any greater depth than can be done by the spade alone. For trenching with a view to pulverizing and changing the surface, a trench is formed like the furrow in digging, but twice or three times as wide and deep. The plot or piece to be trenched is next marked off with the line into parallel strips of this width, and, beginning at one of these, the operator digs or picks the surface stratum, and throws it in the bottom of the trench. Having completed with the shovel the removal of the surface stratum, a second, and a third, or fourth, according to the depth of the soil and other circumstances, are removed in the same way, and thus, when the operation is completed, the position of the different strata is exactly the reverse of what it was before. In trenching with a view to mixture and pulverization (Fig. 512.), all that is necessary is to open, at one corner of the plot, a trench or excavation of the desired depth, three or four feet broad, and six or eight feet long. Then proceed to fill this excavation from one end by working out a similar one. In this way proceed across the piece to be trenched, and then return, and so on in parallel courses to the end of the plot, observing that the face or position of the moved soil in the trench must always be that of a slope, in order that whatever is thrown there may be mixed, and not deposited in regular layers as in the other case. To effect this most completely the operator should always stand in the bottom of the trench, and first picking down and mixing the materials, from the solid side (a), should next take them up with a shovel, or throw them on the slope or face of the moved soil (b), keeping a distinct space of two or three feet between the sides.

For want of attention to this, in trenching new soils for plantations, or other purposes, it may be truly said that half the benefit derivable from the operation is lost. In general in trenching, those points which were mentioned under digging, such as turning breaking, dunging, &c. required to be attended to, and sometimes an additional object—that of producing a level from an irregular surface—is desired. In this case double care is requisite, to avoid forming subterraneous basins or hollows, which might retain water in the substratum, at the bottom of the moved soil, and also to mix inferior with better soil, &c. where it becomes requisite to penetrate into depositions of inferior earthy matters. The removal of large stones, rocks, or roots, from ground trenched for the first time, will be treated of under Improvement of Lands lying waste. (Book III. Chap. IV.)

5127. *Ridging* is a mode of finishing the surface, applicable either to dug or trenched grounds, which, when so finished, are called ridge-dug or ridge-trenched. Instead of being formed with an even surface, ridged grounds are finished in ridges or close ranges of parallel elevations, whose sections are nearly equilateral triangles. Hence, supposing the triangles to touch at their bases, two thirds more surface will be exposed to the influence of the atmosphere and the weather, than in even surfaces.

5128. *Forking* The fork is composed of two or three separate, parallel, and uniform wedges, joined so as to form one general blade, which is acted on like the spade, by means of a shoulder or tilt for thrusting it into the matters to be forked, and a lever or handle

for separating and lifting them. Forking is used for two purposes. *For pulverising the soil among growing crops, and for moving vegetable substances, such as faggots of wood, sheaves of corn, hay, manure, &c.* In the first case the operation is similar to digging, the only difference being that pulverisation is more attended to than reversing the surface; in the other, the fork separates chiefly by drawing and lifting, hence, for this purpose, a round-pronged or (dung) fork produces least friction during the discharge of the forkful and refinement, and a broad-pronged fork separates and lifts the soil more readily. Dry weather is essentially requisite in forking soils, and most desirable for spreading manures, but dunghills may be turned during rain with no great injury.

5129. *Dragging out dung or earth* is performed by the dung-drag, and is adopted in the case of distributing dung from a cart in regular portions or little heaps over a field. When lime in a state of pulverisation, earth, or sand, is to be distributed in the same way a scraper or large hoe is used and sometimes, for want of these, the dung-drag, aided by the spade or common hoe.

5130. *Hand-hoeing* is performed by drawing or thrusting the wedge or blade of the draw or thrust hoe along the surface of the soil, so as to cut weeds at or under the surface, and slightly to pulverise the soil. It is used for four purposes, sometimes together, but in general separately. First, to loosen weeds or turn out plants, so that those hoed up may die for want of nourishment, or be gathered or raked off, for which purpose either the thrust or draw hoe may be used. The second, to stir the soil, and for this purpose, when no weeds require killing, the pronged hoe is preferable, as being thrust deeper with less force, and as less likely to cut the roots of plants. The third is to draw up or accumulate soil about the stems of plants, for which purpose a hoe with a large blade or shovel will produce most effect, and the fourth is to form a hollow gutter or drill in which to sow or insert the seeds of plants, for which a large or small draw-hoe may be used, according to the size of the seeds to be sown. The use of the hoe for any of the above purposes requires dry weather.

5131. *Hoeing between rows of crops* is sometimes performed by what is called a hoe-plough, which is a small plough having a share with double flus, drawn by one man and pushed by another. It is in use in India, and is sold in London under the name of the Indian hoe-plough, but it is more for the exercise of amateurs on free soils than for useful culture. In this way a master may exercise both himself and his valet, and clear his potatoes or turnip crop at the same time. The Dutch have a hoe (fig. 511) which is drawn and pushed at the same time, for the purpose of cleaning walks, or scraping turf or mud from roads or court-yards.

5132. *Hand-raking* is performed by drawing through the surface of the soil, or over it, a series of small equidistant wedges or teeth, either with a view to minute pulverisation, or to collecting herbage, straw, leaves, stones, or such other matters as do not pass through the interstices of the teeth of the rake. The teeth of the rake being placed nearly at right angles to the handle, it follows that the lower the handle is held in performing the operation, the deeper will be the pulverisation, when that is the object, and, on the contrary, that the higher it is held, the interstices being lessened, the fewer extraneous matters will pass through the teeth. The angle at which the handle of the rake is held must therefore depend on the object in view. The medium is forty-five degrees. For all raking, dry weather is essentially requisite, and, for raking hay the angle which the handle of the rake makes with the ground's surface ought to be fifty degrees.

5133. *Scraping* may be described as the drawing of a large broad blunt hoe along the surface, for the purpose of collecting loose excrementitious or other useless or injurious matters from roads, yards, or from grassy surfaces to be rolled or mown. The Dutch hoe (fig. 515.) is a good road and lawn scraper.

5134. *Sweeping* is a mode of scraping with a bundle of flexible rods, twigs, or wires, which enters better into the hollows of irregular surfaces, and performs the operation of cleaning more effectually. In agriculture it is used in barns and in stables, though shovelling is generally sufficient for the common stable and ox-house.

5135. *Sieving, or sifting, earth or gravel*, is an operation performed with the gravel-sieve or earth screen, for separating the coarser from the finer particles. The materials require to be dry well broken, and then thrown loosely on the upper part of the screen, which, being a grated inclined plane, on sliding down it, the smaller matters drop through while the large ones pass on and accumulate at the bottom. In sifting, the same effect is more completely, but more laboriously, produced, by giving the sieve a circular motion with the arms.

5136. *Gathering* is a very simple operation, generally performed by women and children, as in taking up potatoes or other roots, or picking up stones, weeds, or other matters considered injurious to the surface on which they lie or grow.

5137. *Cleaning roots or other matters* is generally performed by washing, and, on

a large wheel, by the root-washing machine, which has already been described, together with the mode of using it.

3138. Various manual labours and operations might be added; such as slicing turnips; chopping them with the chopping-hoe (3572.) in the fields, cutting straw or hay into chaff; bruising beans or other grain, or wrens, or thistles, between rollers, pushing a drill-barrow, &c.; all which require only bodily exertion, with very little skill, being performed by the aid of machines, which, in describing, we have also indicated the mode of working. (2537 to 2583.)

### SECT. III. *Agricultural Operations with Plants.*

3139. *Agricultural operations with the vegetable kingdom* rank higher than those with the soil or machines, as requiring not only strength, but some of them a considerable degree of skill.

3140. *Weeding*, however simple an operation, requires a certain degree of botanical skill to know what to weed or extract. These are such plants as it is not desired to cultivate. The operation is performed in various ways: by the hand simply, by the hand, aided by a broad-pointed knife, or a bat of iron hoop by the hand, aided by gloves tipped with iron by pincers, as in weeding tall weeds from growing corn, or close-hedges, or out of water and by the aid of forks, spuds, or other weeding tools. In weeding, it is essential that the weeder know at sight the plants to be left from such as are to be removed, which in agriculture is generally a matter of no difficulty, as, however numerous the weeds, the cultivated plants are but few. In weeding ferns, thistles, nettles, &c. from pasture lands, it has been found that breaking or bruising them over renders the roots much less liable to spring again the same season, than cutting or even pulling them up. For this sort of weeding the pincers seem well adapted.

3141. *Thinning* or reducing the number of plants on any surface is sometimes performed by hand, but most generally with the hoe. Thinning, to be perfectly performed ought to leave the plants at regular distances; but as this can seldom be done, owing to the irregularity with which seeds come up, whether sown in drills or broadcast, an attempt to compensate the irregularity is made by a similar irregularity in the distances allowed between the plants at such places. Thus, if turnips in rows are to be thinned out to nine inches' distance in the row and a blank of eighteen inches or two feet occurs, the last two plants on each side of the blank may be left at half the usual distance, or less, by which means each plant having ample room on one side, they will grow nearly as large as if left at the usual distance. The same principle is to be attended to in thinning broadcast crops, or trees in a plantation. Thinning may be performed in moist weather but dryness is greatly to be preferred, especially where the hoe is used.

3142. *Planting* is the operation of inserting plants in the soil with a view to their growth, and the term is also applied to the insertion of seeds, roots, or bulbs, when these are inserted singly.

3143. *Planting as applied to seeds and tubers*, as beans, potatoes, &c. is most frequently performed in drills, but sometimes also by making separate holes with the dibber. In either case, the seeds or sets are deposited singly at regular distances, and covered by raking or harrowing, with or without pressure, according to the greater or less looseness of the soil, and to its dryness or moisture. In general, planting seeds or tubers in drills, or in single openings made by a draw-hoe or spade, is greatly preferable to planting with the dibber because, in the latter case, the earth can seldom be placed in close and somewhat firm contact with the seed or set,—a circumstance essential to its speedy germination and vigorous future growth.

3144. *Planting as applied to plants already originated*, is commonly termed *transplanting*. Transplanting may be considered as involving four things: first, the preparation of the soil to which the plant is to be removed; secondly the removal of the plant; thirdly, its preparation; and, fourthly, its insertion in the prepared soil. Preparation of the soil implies, in all cases, stirring, comminution, and mixing; and sometimes the addition of manure or compost, according to the nature of the soil and plants to be inserted. The removal of the plant is generally effected by loosening the earth around it, and then drawing it out of the soil with the hand. In all cases avoiding, as much as possible, to break or bruise, or otherwise injure, the roots. In the case of small seedling plants, merely inserting the spade, and raising the portion of earth in which they grow, will suffice; but, in removing large plants, it is necessary to dig a trench round, or on one side of the plant. In some cases, the plant may be lifted with a ball or mass of earth, containing all or great part of its roots; and in others, as in the case of large shrubs or trees, it may be necessary to open the soil around them a year previously to their removal, and cut the larger roots at a certain distance from the plant, in order that they may throw out fibres to enable them to support the operation of transplantation. By two years previous preparation, and the use of a machine to be afterwards described, very large trees of such kinds as stone may be removed; but ruinous trees seldom succeed.

5145. *The preparation of the plant consists in pruning its roots and top, or shoots.* In the smallest seedlings, such as cabbage-plants and -cherms, all that is necessary is to shorten a little the tap or main root; but in seedlings of trees two or three years old, or in transplanted or large trees, several of the side shoots will require to be shortened, and also the roots, always proportioning what is taken off the top or shoots, to what has been taken from the root, that the latter may be duly fitted to support the former.

5146. *The insertion of the removed plant in the prepared soil is performed by making an excavation suitable to the size of the plant's root, inserting it therein, filling up the interstices with fine earth, and then compressing the whole by the hand, dibber, foot, or, what is best, by abundant watering.* Plants should not be inserted deeper in the soil than they were before removal, they should be placed upright, and the same side should be turned towards the sun as before. The fibrous roots should be distributed equally round the stem among the mould or finer soil, and the most difficult and important part of the whole is to compress the earth about the roots without crowding them or injuring them by bruises. The only effectual way of attaining this end is, after carefully spreading the fibres, and distributing them as equally as possible among the mould, to give abundant waterings, holding the vessel from which the water is poured as high as possible, so as to consolidate the earth by that means, rather than by compression with the foot. On an extensive scale, however, this cannot be done, and in planting seedlings or cuttings it is not required, as these have few and short fibres, and may be firmed sufficiently by the planting instrument or the foot. It should never be forgotten that, in all planting, it is an essential point to have the earth firmly compressed to the roots, and especially to the lower parts or extremities. Any one may be convinced of this, by planting one cabbage loosely, and compressing the root of another well with the dibber at the lower part or, instead of a cabbage, try a cutting say of gooseberry, elder or vine both no doubt will grow, but the growth of the plant or cutting compressed at the lower extremity will be incomparably more vigorous than that of the other.

5147. *Watering becomes requisite for various purposes as alimnt to plants in a growing state as support to newly transplanted plants for keeping under insects and keeping clean the leaves of vegetables.* One general rule must be ever kept in mind during the employment of water that is, never to water the top or leaves of a plant when the sun shines. A moment's reflection will convince any one that this rule is agreeable to the laws of nature, for during rain the sun's rays are intercepted by a screen of fog or clouds. All artificial watering, therefore, should be carried on in the evening, or early in the morning unless it be confined to watering the roots in which case, transplanted plants, and others in a growing state, may be watered at any time, and, if they are shaded from the sun, they may also be watered over their tops.

5148. *Sowing is the operation of dispersing seeds over the surface of the soil with a view to their future vegetation and growth.* Where seeds are deposited singly, they are said to be planted, as in the case of dibbling wheat or beans where they are dropped in numbers together they are said to be sown. When dropped in numbers together in a line they are said to be drilled or sown in a row, and when scattered over the general surface by the hand, they are said to be sown broadcast.

5149. *In broadcast sowing the operator being furnished with a basket (fig. 525), or snecful of seed hanging on his left side, takes out a handful with his right hand, and disperses it by a horizontal and rather rising movement of the arm to the extent of a semicircle, gradually opening his hand at the same time.* The most usual practice, when land is laid up in ridges of equal breadth, and not too wide, as five or six yards, is that of dispersing the seed regularly over each land or ridge, in once walking round the seedman by different casts of the hand, sowing one half in going, and the other in returning. In doing this, it is the custom of some seedsmen to fill the hand from the basket or bag, which they carry along with them, as they make one step forward, and disperse the seed in the time of performing the next, while others scatter the seed or make their casts, as they are termed by farmers, in advancing each step. It is evident, therefore, that, in accomplishing this business with regularity and exactness, there is considerable difficulty the proper knowledge and habit of which can only be acquired by experience. It is consequently of importance for the cultivator to perform the operation himself or to be careful in selecting such persons as are conversant with the business, as he may otherwise incur much unnecessary expense in the waste of seed, and run considerable risk in respect of his crops.

5150. *Sawing.* The saw is a conjoined series of uniform wedges, which, when drawn or thrust in succession across a branch or trunk, gradually wear it through. In performing the operation, the regularity of the pressure and motion are chiefly to be attended to. In green or live shoots, the double-toothed saw lessens the friction on the sides of the plate, by opening a large channel for its motion. Where parts are detached from living trees, the living section ought generally to be smoothed over with a knife, chisel,

or file; and a previous precaution in large trees is to cut a notch in the lower part of the branch immediately under and in the line of the section, in order to prevent any accident to the bark, when the amputated part falls off. Sawing is a coarser mode of cutting, moving, or shaving; or a finer mode of raking, in which the teeth follow all in one line.

5151. *Cutting* is performed by means of a very sharp wedge, and either by drawing this through obliquely or across the body to be cut, as in using the knife; or by pressing or striking the axe or hedge-bill obliquely into the body, first on one side of an imaginary line of section, and then on the other, so as to work out a trench across the branch or trunk, and so effect its separation. The axe, in gardening, is chiefly used in felling trees, and for separating their trunks, branches, and roots, into parts. The knife is extensively used for small trees, and the hedge-bill and chisel for those of larger size. In amputating with the knife, one operation or draw-cut ought generally to be sufficient to separate the parts and thus ought to be made with the knife sufficiently sharp, and the motion so quick as to produce a clean smooth section, with the bark unjured.

5152. Every draw-cut produces a smooth section, and a fractured or bruised section; and one essential part of cutting living vegetables, is to take care that the fractured section be on the part amputated. Another desirable object is, that the section of the living or remaining part should be so inclined (Fig. 514 a) as not to lodge water or overflowing sap, and so far turned to the ground (d) or to the north, as

not to be struck by the direct rays of the sun. To accomplish both these purposes, as well as to make sure of having the fractured section on the part amputated, the general practice is to cut from below, or from the under edge of the branch or shoot, unless the position of the leading bud occasions a deviation from the rule (b). The cuts should also be made, in all shoots of not more than three or four years old, within from one fourth to half an inch, or a little more, of the bud intended to take the lead when this is not done, and half an inch or more of shoot is left without a bud (c and e) the consequence is, the stump dies back to the bud in the course of the season (g) and if not carefully cut off (f), will end in a decaying surface both unsightly and injurious. The bud selected for a leader ought always to be a leaf bud, and in general the plane of the section ought to be parallel to the angle which the bud makes with the stem (d). Exceptions occur in the case of plants with much pith (h) as the vine, elder, &c. in cutting the year-old shoots of which, an inch or more ought to be left, as these always die back a few lines; and thus the leading bud might be injured, if this precaution were not taken. In pruning roots the same principle as far as applicable, ought to be attended to the trunk or stem, when cut over ought to be sloped to the north (f), and the lateral roots cut so as the section may be on the under side (i) and therefore less likely to rot than when the cut from the surface of the ground (j), or is bruised by neglecting to form the smooth section on the attached extremity.

5153. In like manner when pruning a large tree, the section of amputation ought to be made so oblique as to throw off the ruin; as generally as possible, it should be turned from the sun, and rather downwards than upwards, in order to shield it from heat and cracking and whenever it can be done, it should be made near a branch, shoot, or bud, which may take the lead in the room of that cut off, and thus, by keeping the principle of life in action at the section, speedily heal up the wound.

5154. In cutting with the chisel, the blade is applied below the branch to be amputated, so as to rest on the trunk or main branch, and a quick blow with a mallet is given to the handle of the chisel by the operator or his assistant. If this does not effect a separation, it is to be repeated. In forest-pruning it is often advantageous to make one cut with the chisel on the under side of the branch and then saw it through with the forest-saw from the upper.

5155. *Clipping* is an imperfect mode of cutting, adapted for expedition, and for small shoots. The operation is effected by bruising or crushing along with cutting, and, in consequence, both sections are fractured. In agriculture, it is chiefly applied for keeping hedges in shape; but the hedge-knife, which operates by clean rapid draw-cuts given always from below, is generally preferable, as not crushing the live ends of the amputated shoots. The new pruning-shears and the overrunner, it is to be observed, by producing cuts much more like the draw-cuts of knives, are greatly to be preferred to the common hedge-shears.

5156. The best seasons for moving, cutting, or clipping living trees, are early in spring and in midsummer. Early in autumn, trees are apt to bleed; later, and in winter, the section is liable to injury from the weather but trees pruned early in spring remain only a short period before they begin to heal and in those pruned at midsummer, wounds heal immediately. There are, however, exceptions as to spring-pruning in evergreens, cherries, and other gumiferous trees, and summer-pruning is but ill adapted for forest-work or trees in crowded society.

3157 *Splicing* is an operation generally performed on roots of trees remaining in the soil for the purpose of facilitating their eradication. The wedge, in its simplest form, and of iron, is driven in by a hammer or mallet, till it produces fracture and separation. when the parts are removed as detached, &c.

3158. *Pruning*, or the amputation of part of a plant with the knife, or other instrument, as practised for various purposes, but chiefly on trees, and more especially on those of the fruit-bearing kinds. Of two adjoining and equal-sized branches of the same tree, if the one be cut off, that remaining will profit by the sap which would have nourished the other and both the leaves and the fruits which it may produce will exceed their natural size. If part of a branch be cut off which would have earned a number of fruits, those which remain will set, or fix better and become larger. On the observation of these facts is founded the whole theory of pruning which, though, like many other practices of culture it cannot be said to exist very obviously in nature is yet the most essential of all operations for the culture of fruit produced on trees.

3159. The objects of pruning may be reduced to the following: promoting growth and bulk; lessening bulk; modifying form; adjusting the stem and branches to the roots; renewal of decayed plants or trees and removal or cure of diseases.

3160. *Pruning for promoting the growth and bulk of a tree* is the simplest object of pruning and is that species which is chiefly employed by nursery men with young trees of every description. The art is to cut off all the weak lateral shoots, that the portion of sap destined for their nourishment may be thrown into the strong ones. In some cases, besides cutting off the weak shoots the strong ones are shortened, in order to produce three or four shoots instead of one. In general mere bulk being the object, upright shoots are encouraged rather than lateral ones except in the case of trees trained on walls, where shoots are encouraged at all angles, from the horizontal to the perpendicular but more especially at the medium of 45 degrees. In old trees, this object is greatly promoted by the removal, with the proper instruments, of the dead outer bark.

3161. *Pruning for lessening the bulk of the tree* is also chiefly confined to nursery practice, as necessary to keep unsold trees portable. It consists in little more than what is technically called *heading down*; that is, cutting off the leading shoots within an inch or two of the main stem, leaving, in some cases some of the lower lateral shoots. Care is taken to cut to a leaf bud, and to choose such from among the side, upper or under buds of the shoot, as the succeeding year's shoots may be wanted, in radiated lines from the stem, or in oblique lines in some places to fill up vacancies. It is evident that this unnatural operation, persisted in for a few years must render the tree knotty and unsightly and in some fruits at least, it is apt to generate canker and gum.

3162. *Pruning for modifying the form of the tree* embraces the management of the plant from the time of its propagation. In rearing trees planted for timber it is desirable to throw the timber produced, as much as possible, into long compact masses, and hence pruning is employed to remove the side branches, and encourage the growth of the bole or stem. Where this operation is begun when the trees are young it is easily performed every two or three years, and the progress of the trees under it is most satisfactory when however it is delayed till they have attained a timber size, it is, in all cases, much less conducive to the dry red end, and sometimes may prove injurious. It is safer in such cases, to shorten or lessen the size of lateral branches, rather than to cut them off close by the stem, as the large wounds produced by the latter practice either do not contract at all, or not till the central part is rotten and has contained the timber of the trunk. In all cases, a moderate number of small branches, to be taken off as they grow large are to be left on the trunk to facilitate the circulation of the sap and juices. Where timber-trees are planted for shelter or shade, unless intermixed with shrubs or coepes it is a silent pruning must be directed to clothing them from the summit to the ground with side branches. In avenue, and hedgerow trees, it is generally desirable that the lowest branches should be a considerable distance from the ground. In trees intended to conceal objects, as many branches should be left as possible and in others, which conceal distant objects desired to be seen, or injure or conceal near objects, the form must be modified accordingly. In all these cases, the superfluous parts are to be cut off with a clean section, near a bud or shoot if a branch is shortened or close to the trunk if it is entirely removed the object being to facilitate circulation.

3163. *Pruning for adjusting the stem and branches to the roots* is almost solely applicable to transplanted trees, in which it is an essential operation, and should be performed in general in the interval between removal and replanting when the plant is entirely out of the ground. Supposing only the extremities of the fibres broken off, as is the case with very small plants and seedlings, then no part of the top will require to be removed; but if the roots have been broken or bruised in any of their main branches or ramifications, then the pruner estimating the quantity of root of which the plant is deprived by the sections of fracture and other circumstances, peculiar and general, will be able to form a notion of what was the bulk of the whole roots before the tree was disturbed. Then he may state the question of lessening the top to adjust it to the roots, thus — as the whole quantity of roots which the tree had before removal is to the whole quantity of branches which it now has, so is the quantity of roots which it now has to the quantity of top which it ought to have. In selecting the shoots to be removed regard must be had to the ultimate character the tree is to assume, whether a standard or trained fruit-tree, or ornamental bush. In general, bearing-wood and weak shoots should be removed, and the stronger lateral and upright shoots, with leaf or shoot-eyes left.

3164. *Pruning for renewal of the head* is performed by cutting over the stem a little way, say its own thickness above the collar or the surface of the ground. This practice applies to old cedar-beds coppice woods, and to young forest-trees. Sometimes also it is performed on old or ill-thriving fruit-trees which are headed down to the top of their stems. This operation is performed with the saw and better after scarification, as in cutting off the broken limb of an animal. The live section should be smoothed with the chisel or knife, covered with the bark and coated over with grafting-clay or any convenient composition, which will resist drought and rain for a year. Those who are advocates for pruning when the sap is dormant, will not of course be able to perform the operation of scarification, and covering the section with bark.

3165. *Pruning for curing diseases* has acquired much celebrity since the time of Forsyth, whose amputations and scarifications for the canker together with the plaster or composition which he employed to protect the wounds from air are large in his *Treatise on Fruit-Trees*. As the cause of all vegetable diseases either have their origin in the weakness of the individual or induce a degree of weakness; hence to amputate a part of a diseased tree, is to strengthen the remaining part, because the roots remaining of the same force, the same quantity of sap will be thrown upwards as when the head and branches were entire. If the disease is constitutional, or in the system this practice may probably, in some cases, communicate to the tree so much strength as to enable it to throw it off. If it be local, the amputation of the part will at once remove the disease, and strengthen the tree.

3166. *Mowing* is the operation of cutting down corn grass, and other herbage crops, with the scythe. It requires great force in the operator, and also a twisting motion of

the body which brings almost every muscle into action, and is in short one of the most severe of agricultural labours. The chief art consists in cutting the crop as close to the surface of the ground as possible, and perfectly level, pointing the swaths well out so as to leave scarcely any ridges under them. In the mowing of grain crops, scythes shorter in the blade than the common ones, and to which either a cradle or two twigs of osier put semicircular-wise into holes made in the handles near the blades, in such a manner that one semicircle intersects the other, are made use of. Commonly in mowing barley, oats, or other grain, the corn is on the right hand of the workman but M. de Lisle adopted something like the Hainault method of mowing wheat (2479) in which the corn was at his left hand he mowed it towards, bearing the corn he cuts on his scythe, till it comes to that which is standing, against which it gently leans. After every mower a gatherer follows, who may be a lad, or a woman. The gatherer keeps within five or six feet of the mower and being provided either with a hook or stick about two feet long, gathers up the corn, making it into parcels, and laying it gently on the ground; this must be done with speed, as another mower immediately follows, and to every mower there is a particular gatherer. To do this work properly the mower should turn but one track with his feet, advancing in a posture nearly as if he was going to fence, one foot chasing the other. In this manner the standing corn is mowed and the workman should take care to have the wind at his left, as it bears the corn towards the scythe, and causes it to be cut nearer the ground. When wheat is bent, the workman takes the corn as it presents itself to him, which has the same effect as if the wind was at his left side. When it is laid, it is more troublesome to the gatherer because the cut corn is apt to be mixed with that which is standing but a good mower takes the advantage of the wind, and cuts it against the way it is laid. No particular directions can be given for corn that is lodged and entangled, unless it be to take it as it is inclined, as if the wind were on the back of the mower.

5167 The usual method of mowing grass is the same as for grass, the scythe only having a cradle or bow fixed upon the heel of the handle. (fig. 236) In the 'practice of most districts, the scythe is swung horizontally or nearly level, leaving the stubble of almost an even height; or if it rise on either side, forming what are called swath-balks the butts of the swaths are suffered to rest upon them, the heads or ears of the corn falling into the hollow or close mown part of the preceding swath width. They are of course liable, in a wet season, not only to receive an undue portion of rain water, but to be fouled with the splashing of heavy showers. But in the Kentish practice, which is said to excel those of other districts, the position of the swaths is different. Here, the heads of the corn rest on the top of the swath-balk, provincially the *beever* which is left of extraordinary height, as ten to fifteen inches so that the wind has a free circulation beneath the swaths. The workman, in performing this judicious operation, proceeds with his right foot forward, entering the point of his scythe with a downward stroke, and raising it as abruptly out, bringing the handle round to the left until it forms nearly a right angle with the line of the swath, carrying the corn in the cradle three or four feet behind the place where it grew lifting it high, and letting it fall on the beever behind his left foot, and in the position above described. The disadvantages of this method are, the loss of some straw the incumbrance arising from the length of stubble, and a little additional labour but in a district where cattle are not numerous, the loss of straw is not felt, and in any country the principle of laying the heads instead of the butts of the corn upon the swath-balk, whether left high or low might be well adopted."

5168 In the cutting of grass crops for the purpose of being converted into hay it is necessary that they be in the most suitable states of growth and maturity for affording the best and most nutritious fodder. With this view they should neither be cut at too early a period, nor suffered to stand too long as in the former case there will be considerable loss in the drying, from the produce being in so soft and green a condition, and in the latter from a large proportion of the nourishing properties being expended. Grass, before it becomes in full flower while the rich saccharine juice is in part retained at the joints of the flower-stems, is in the most proper condition for being cut down, as at that period it must contain the largest proportion of nutritious matter but in proportion as the flowers expand and the seeds ripen, the juice is taken up to constitute the meal or starch of the seed lobes, and is thus either dispersed upon the land, or fed upon by birds. the grass stems with their leaves being left in a similar situation to that of the straw of ripened grain. But there are other circumstances, besides those of ripeness, to be attended to in determining the period of cutting crops of grass, as in some cases when they are thick upon the ground the bottom parts become of a yellow colour before the flowering fully takes place under such circumstances it will often be the most advisable practice to mow as soon as the weather will possibly admit for if this be neglected, there will be great danger of its rotting, or at any rate of its acquiring a disagreeable flavour, and of becoming of but little value. Where grass is very tall, as is

often the case in moist meadows, it is liable to fall down and lodge, by which the same effects are produced.

3169. In cutting rough or second crops of grass, more attention will be requisite than in the first, as the crops are mostly much lighter and more difficult to cut, the scythe being apt to rise and slip through the grass without cutting it fairly except when in the hands of an expert workman. Crops of this sort should always be cut as much as possible when the dew is upon them and as soon as ever there is a tolerable growth as, by waiting the season is constantly getting more unfavourable for making them into hay and when not well made, this hay is of little or no value. When the grass has been decided to be in the proper condition for being cut down, a set of mowers proportioned to the extent of the crop should be immediately provided. In some districts, it is the custom to pay these labourers by the day but a better and more general practice is to let the work at a certain price by the acre. The extent or proportion of ground that can be mown in any given space of time must obviously vary much according to the nature of the ground, the fullness of the crop, and the goodness of the workman but in general an acre is supposed a full day's work for an expert mower.

3170. The mowing of weeds and coarse tussocks of grass in pasture should take place before they come into flower, or at all events before they ripen their seed. Bruising or clipping with a sort of blunt wooden shears is considered preferable for ferns, thistles, and nettles (3140), as they are said not to spring up again the same season, which they are apt to do if cut over with the clean cut of the scythe.

3171. The mowing of weeds in rivers and ponds is done in the usual way from a boat, in which the operator stands, and is rowed forward by another as required. Sometimes scythe-blades are tied or rivetted together and worked by means of ropes like a saw from one shore to the other but the first mode is generally reckoned the best, even in public canals, and is unquestionably so in agriculture.

3172. The *Harnault* mowing is a process which is exclusively applicable to corn crops it has been long practised in Flanders, and though various attempts have been made at different times and places to introduce it to this country and notwithstanding the great advantages promised, it is still little known. We have already described the implement, and the mode of using it, and suggested reasons for its not being more generally employed (3479). The breadth of corn cut at every stroke are carried forward by the joint operation of the blade and the hook and collected at the left hand of the mower where he leaves them standing almost erect, but leaning to the left against the standing corn. When as much is cut as will make a sheaf the mower turns to the left so as to face the standing corn, introduces his hook behind the middle of the leaning parcels, and at the same time the scythe points near the bottom then mowing sideways to the left, returning over the ground he has mown, he draws and collects the cut corn, still by means of the hook and scythe preserving the erect position of the straw to the place where the last collecting operation ended then wheeling round to the left, with the hook still embracing the middle of the whole cut corn, he stops the motion of the scythe whilst the hook still moves forward to the left, so as to overset the corn and lay it evenly along on the stubble with the ears towards the right, ready for the binder. In oversetting the collected corn he uses his left foot if necessary. The mower now advances to the front, and commences the cuts for a new sheaf as before always working towards the standing corn and not from it.

3173. *Reaping* is the operation of cutting corn with the hook or sickle, the former called provincially bagging, the latter shearing or reaping. The operation of reaping is most general in the northern counties. The corn is cut in handfuls with the sickle (2481) and these are immediately deposited upon bands, formed by twisting together a few of the stalks of the corn at the ends next the ears, and afterwards bound up into sheaves, in order to their being set up into shocks or battocks. The method is in most instances adopted with the wheat and rye crops in every part of the island, as it is difficult to cut without much loss from the shedding of the grain and, in addition, it is of great advantage to have these sorts of crops bound up regularly into sheaves, the straw being much better.

3174. In *bagging*, the operator hooks up the corn towards him, and then lays it on bands as in reaping. By this mode corn is cut lower than by reaping with the sickle, but rather more straws drop unless great care is taken.

3175. *Sheaving and shocking* or, as termed in the north, binding and stooking, are operations performed for the most part immediately after the corn is cut. In binding it is tied up in sheaves or bundles by the bands already mentioned and in shocking or stooking, the sheaves are set on end in pairs leaning against each other, and covered or otherwise by what are called heading sheaves, laid on the upright ones so as to cover and protect the ears from the weather, and act as a roof to the shock or stook. The number of sheaves brought together in a stook, and even the modes of placing them, vary in dif-

ferent districts. The operation is performed with most care and neatness in the wet climates of the north.

§176. *Gaiting*, or *gaitring*, as it is called in Northumberland, is an operation of much nicety in the performance, and in a damp climate of great consequence in its results. In the upland parts of Northumberland, it is performed in the following manner with the crops of oats, frequently with those of barley and sometimes with those of wheat — The gaiter follows immediately after about eight or nine sheaves have been cut and laid down; the corn being laid into the band near the tops or spikes of the corn, he seizes the ends of the band with each hand, brings the gaitring (sheaf) up to the left knee, gives the band a slight and peculiar twist, and then sets the sheaf up singly; but in doing so he gives it a half turn round, which makes the skirts fly out and gives it exactly the appearance of the straw cover of a bee-hive if properly done, the band should be so loose that the master can thrust his hand easily through the middle. The utility of this practice is that no rain can lodge, and the corn therefore never sprouts unless the band has been tied too tight. It also wins [dries] and is fit for the stack sooner. Gained sheaves are not good to keep standing in stormy weather some, therefore, now set three gained sheaves together, which keeps them up they are always sound before they are carted to the stack but frequently they are not stoked. (*J. C. R. near Alnwick*.)

§177. *An improved method of setting up sheaves of corn* is thus described. Take a stake about twice the height of a sheaf, and drive it six inches into the ground at its thicker end, in an upright position, and around this place eight sheaves in the usual manner: two more sheaves are then to be bound together at the straw end, and being inverted, are to be thrust down on the top of the stake, so that it shall pass up into the centre of the bound part, and their lower ends being then spread out so as to cover the lower sheaves will protect them from wet in the manner of a hood sheaf. (*Gard. Mag. vol. v*.)

§178. *In the reaping of grain crops* whether the sickle, hook, or scythe is employed for the purpose, there is much difference in the height at which the crops are cut in different places. In some it is the practice to have the business performed in as close a manner as possible while in others a stubble of eight, ten, and fifteen inches or more is left. These different practices have their advocates one party supposing that the work proceeds more slowly where it is executed in so close a manner, while the other contends that the contrary is the case. But as the stubble which is left is not only useless to the land, but in many cases very troublesome in its succeeding culture, being frequently under the necessity of being removed, it would seem to be the best as well as cheapest practice, to have the business constantly executed in a close manner. By this means the agriculturist will not only have more litter at command for the bedding of his yards, stalls, and other places, and consequently an increase of manure, but with much less waste of grain, and at the same time be freed from the trouble and expense of removing the stubble. It has, indeed, been fully shown, by a careful trial made with the view of ascertaining the difference between high and low reaping that the advantage is considerably in favour of the latter.

§179. *The sickle and the scythe in reaping grain crops* have each their advantages and disadvantages. In the first manner the crops are deposited with more regularity and exactness, and consequently bound into sheaves with greater facility and despatch. Besides, in many cases, less loss is incurred by the shedding of the grain in the time the work is performing but the labour is executed with greater difficulty and trouble. Reaping by the scythe possesses the superiority of being more expeditious, and of being performed to any degree of closeness that may be required while it has the evident disadvantage of leaving the cut grain in a more irregular and uneven situation by which it is rendered less fit for being bound up into sheaves, which in many cases is an inconvenience of great consequence. Another objection is, that the ears not being so regularly presented to the rollers of the threshing-mill the threshing is not done so perfectly. When the grain has attained a high degree of ripeness, there may likewise, be great loss sustained, by its being shed during the operation in this way of reaping or cutting the crop. Where this method is practised, it is, however not unfrequently bound into sheaves, though the more common custom is to let it remain in the rows or swaths till fit for being put into the stack. It is generally the practice to cut it inwards against the crop on which it rests. In the other case, it is cut in the manner of grass for hay. It is obvious, therefore, that where operators are procured with difficulty this mode of reaping is the most advisable while, under the contrary circumstances, the former may be had recourse to with more advantage, as the work may be executed in a neater and more exact way.

§180. *Reaping, whatever mode be adopted, is often let by the acre* to persons that go about for harvest work, and it may, in many cases, be best performed in this manner but great attention should be paid by the cultivator to see that the grain is cut and bound up in a proper method, and that the work is not performed in improper weather. The prices vary according to the nature of the crops, the season, and other circumstances. In

Forfarshire, and in some other parts of the north of Scotland, reaping is performed by the *threave*, which consists of twenty four sheaves. By this practice it is the interest of the reapers to cut as close as possible, because they know, that the lower ends of the stalks fill the sheaf better than the upper parts.

3181. *Pulling* is a mode of taking a crop applicable chiefly to flax and hemp. These are pulled in handfuls, the earth beat and shaken from their roots, and after the handfuls have lain a day or more separately they are collected together and tied in bundles. In the case of hemp, it being a diocious plant, the male stalks are pulled some weeks before the others. Dry weather is preferable for the operation.

3182. *Digging up or forking up* is occasionally resorted to for taking crops of roots, as potatoes, carrots, &c. In performing this operation, the principal thing is to avoid cutting or bruising the roots with the spade or fork, and to separate the roots from the soil by first lifting up the spudful and then throwing it down in such a way as to break and scatter it, and bring to light the roots or tubers. When crops of this sort are planted in rows, they are frequently raised by a plough, the coulter being withdrawn

#### Sect. IV Mixed Operations performed by Manual Labour

3183. *The mixed agricultural operations* differ little from the last as to the skill or strength required in the operator they are chiefly ropemaking thatching, turning straw or hay drawing or sorting straw flail threshing, hedging and ditching, weighing, measuring, stack-building, sheep-shearing, paring and burning turf, burning clay, and forming compost soils or manures.

3184. *Straw rope making* is an operation which requires two persons when performed in the usual manner with a crook (fig 222) In this case the person who forms the rope is stationary, and the twister moves from him backwards the length of the rope but if the crook is turned by machinery as, for example, by a movement from a threshing machine or by a detached machine turned by hand (fig 223) then the person who forms the rope moves backwards as he lets out the material to be twisted. These sorts of ropes are commonly made of oat or rye straw but they are also formed of coarse hay or rushes, long moss, ferns, &c. In all cases the material requires to be moistened and thoroughly mixed together before it is made use of by the ropemaker

3185. *Thatching* is the operation of covering the roofs of buildings, stacks, &c with some sort of thatch It is an art that requires considerable care, attention, and practice, to perform it in a proper manner Before this business is begun, it is necessary that the materials, of whatever kind they may be, should undergo some preparation With articles of the straw kind the usual method is this the substances, after being well moistened with water are drawn out in handfuls perfectly straight and even, into regular lengths, and the short straw separated from them leaving them placed in convenient bundles to be carried to the thatcher by the person who has the serving of him.

3186. *The application of thatch to stacks of hay or corn* is performed by different methods, according to the nature of the materials employed. Where long straw is made use of, the operator or workman usually begins at the eaves or bottom of the roof, depositing it in handfuls in regular breadth till he reaches the top, the different handfuls being so placed *endwise* as to overlap each other the upper ends being constantly pushed a little into the bottom parts of the sheaves. In this manner he gradually proceeds, breadth after breadth till the whole of the roof is covered, which is usually done to the thickness of about four or five inches. In order to retain the thatch in its place short sharp-pointed sticks are sometimes thrust in in a slanting direction upwards, and sometimes small sticks sharpened at the ends are bent and thrust in along the top parts and sides but as the water is apt to follow the course of the sticks, it is a better practice to make use of ropes of twisted straw for this purpose. In some cases these are applied only round the bottom parts of the roof and the sides while in others,

515

which is a much better and more secure method, they are applied in such a manner over the whole stacks, as to form a sort of net or loose work of nine or twelve inches in width in the meshes (fig 515), the ends being well fastened either to the sides of the stack under the eaves, or to a rope carried round in that situation on purpose to fasten them to. This method of tying on the thatch should always be had recourse to where the stackyards are greatly exposed to the effects of wind, as without such precautions much injury and loss may frequently be sustained by the farmer It is in common use in Northumberland and northwards.

3187. *In the application of stubble as a thatch for racks*, it is mostly put on by stacking one of its ends into the roof of the stack in a regular and exact manner, so that it may stand very close and thick when the other with such loose straws as may occur is to be cut over or pared off with the thatching knife, or a very sharp tool for the purpose, so

as to form a neat and impenetrable thatch, having the appearance of a newly thatched house-roof (fig. 516) the whole being well secured in its place by short pegs made for the purpose, somewhat in the same way as in the other stacks.

5188 The time of commencing the thatching of hay and corn stacks in England is generally delayed until they have fully settled, as under the contrary circumstance it is sure to rise into ridges afterwards, and by that means admit the water to pass down into them, and of course do much injury to the corn or hay. In Scotland, the stacks are covered with all convenient speed after being built, and a great deal of loss is sometimes sustained, when they are left uncovered even for a few days. When the stack subsides, it is only necessary to tighten the ropes, or in some instances, a part of the ropes are left to be applied, when this subsidence takes place.

5189. In thatching the roofs of houses or other buildings with any of the sorts of straw the same rules are in some respects to be followed, only the materials are to be laid on to a considerable thickness, and be more firmly secured. They are applied in regular narrow slips, or what in some districts are termed *gangs* or *courses*, from the eaves of the building to the ridges, the ladder being moved forward as the work proceeds. The thatch is secured by short sharpened sticks thrust in where necessary and banded sticks sharpened at each end are sometimes made use of near the ridges, being thrust in at each end. In finishing the work, the thatcher employs an iron-toothed rake with which the whole is raked over from the top to the bottom so as to render it completely smooth and even, and take away all the short straws.

5190. The method of thatching with reed, according to Marshall, who seems to have paid much attention to the subject, in his account of *The Rural Economy of Norfolk* is thus "No laths being made use of in laying it a little of the longest and stoutest of the reed is scattered irregularly across the naked spars, as a foundation to lay the main coat upon this partial gauze-like covering is called the *fleeking*

5191 On this *fleeking* the main covering is laid, and fastened down to the spars by means of long rods (previously, *reeds* laid across the middle of the reed, and tied to the spars with rope yarn, or with *bramble bands* which formerly were much in use, but which are now nearly laid aside especially for new roofs.

5192 *Reed is not laid on in longitudinal courses* in the manner that straw thatch is usually put on nor are the whole ends set at once. The workman begins at the lower corner of the roof on his right hand for instance, and keeps an irregular diagonal line or face until he reach the upper corner to his left a narrow row of reeds being nailed across the feet of the spars and some *fleeking* scattered on the thatcher begins to set his eaves, by laying a coat of reed, eight or ten inches thick, with the heads resting upon the *fleeking* and the butts upon the eaves-board. He then lays on his *assay* a rod rather thicker than a large withy) about six or eight inches from the lower points of the reeds, whilst his assistant, on the inside, runs a needle, threaded with rope yarn, close to the spar and in this case, close to the upper edge of the eaves board. The thatcher draws it through on one side of the way and enters it again on the contrary side, both of the way and of the spar the assistant draws it through unthreads it, and with the two ends of the yarn makes a knot round the spar, thereby drawing the way and consequently the reed, right down to the roof whilst the thatcher above beating the way and pressing it down, assists in making the work the firmer. The ass slant having made good the knot below, he proceeds with another length of thread to the next spar and so on till the way he bound down the whole length namely eight or ten feet. This being done another stratum of reed is laid on upon the first, so as to make the entire coat eighteen or twenty inches thick at the butts and another way laid along, and bound down, about twelve inches above the first.

5193 The eaves are adjusted and formed, not square with the spars but nearly horizontal nor are they formed by cutting, but by driving them with a *legget*, a tool made of a board eight or nine inches square, with a handle two feet long, fixed upon the back of it, obliquely in the manner of the tool used by gardeners in beating turf. The face of the *legget* is set with large-headed nails, to render it rough and make it lay hold of the butts of the reeds. Then another layer of reed is laid on and bound down by another way somewhat shorter than the last, and placed eighteen or twenty inches above it and above this another and another continuing to shorten the ways until they be brought off to nothing and a triangular corner of thatching formed. After this, the ways are used their whole length whatever it happens to be, until the workman arrives at the finishing corner. By proceeding in this irregular manner seams between the courses are prevented, and unnecessary shifting of ladders avoided.

5194 The face of the roof is formed and adjusted like the eaves, by driving the reed with the *legget* which operation if performed by a good workman, not only gives the roof a beautiful polished surface but at the same time forms the reed, which being thickest towards the butts, becomes like a tapering pin the tighter the further it is driven.

5195 *Finishing the ridge of the roof* In the case of reed running from four to six or eight feet long the heads meet at the ridge of the roof, whilst the butts are still at a distance from each other. For this reason, as well as for that of the wear being less towards the ridge (the shortest which is generally the worst) reed is saved for the upper part of the roof. But even supposing the uppermost courses to be only four feet long and that the heads (belonging to the two sides) be interwoven in some degree with each other the butts will still remain six or seven feet asunder and the ridge of the roof consequently be left in a great measure exposed to the weather. In order to remedy this inconvenience and to give a finish to the ridge, a coat (previously a roof) of straw is set on in a masterly but in an expensive manner. In this operation, the workman begins, it is observed, by bringing the roof to an angle, with straw laid lengthwise upon the ridge, in the manner in which a reek is topped up and to render it firm, to keep it in its place, and to prevent the wind from blowing it off or ruffling it, he pegs it down slightly with double branches namely cleft twigs two feet long and as thick as the finger, sharpened at both ends, bent double, and perhaps helped by partial chops on the sides to make them hold in the better after being thrust down. This done, the workman lays a coat of straight straw six or eight inches thick across the ridge, beginning on either side at the uppermost butts of the reed, and finishing with straight handfuls evenly across the top of the ridge. Having laid a length of about four feet in this manner he proceeds to fasten it firmly down, so as to render it proof against wind and rain. This is done by laying a *broken legget* (a quarter-of-a reed as thick as the finger, and four feet in length) close to the middle of the ridge, pegging it down at every four inches with a double branch, which is thrust down with

the hands, and afterwards driven with the *legget*, or with a mallet need for this purpose. The middle ligger being firmly laid, the thatcher smooths down the straw with a rake and his hands, about eight or nine inches on one side, and at six inches from the first lays another ligger, and pegs it down with a similar number of double branches, thus proceeding to smooth the straw, and to fasten on liggers at every six inches, until he reach the bottom of the cap. One side finished, the other is treated in the same manner, and the first length being completed, another and another length is laid and finished as the first, until the other end of the ridge be reached. He then cuts off the tails of the straw square and neatly with a pair of shears, level with the uppermost butts of the reed above which the cap (or most properly the *roggles*) shows an saves of about six inches thick, and, lastly, he sweeps the sides of the main roof with a bough of holly when the work is completed.

3196 *Trussing straw or hay* is the operation of binding it in bundles for more convenient transportation. In trussing hay from a rick, it is cut into cubic masses with the hay knife (2484) and tied by a hay rope passing once across each of its sides. If the trusses are intended for the London market, they are weighed with a steelyard, and each truss of old stacked hay must weigh 56 pounds, and of new hay during June, July and August, 60 pounds. We have described a very convenient machine for the operation of trussing (3561).

3197 *Straw is commonly trussed* by tying it into bundles by a band of a handful of straws or a short rope across the middle of the bundle, or by a particular mode of twisting and turning back the two straggling ends of a loose armful of straw and tying these ends in the middle. This mode more easily practised than described, is termed in the north bottling or winding. When wheat-straw or any other sort is to be trussed for thatch it is first drawn into regular lengths, leaving out the refuse, as already alluded to under thatching. In London, the straw sold for litter is always required to be trussed in this manner, and each truss is required to weigh 56 pounds.

3198. *Threshing by the flail* is still a very general practice in most of the southern counties though all intelligent men agree that it is more expensive and less effectual than threshing by a machine. Even on the smallest-sized farms, where a horse machine would be too expensive, either the hand machine or portable machine (3545) might be employed. Besides threshing cleaner and that too in a manner independently of the care of the operators, the work is performed without the aid of expensive threshing floors, goes on rapidly in a more agreeable description of labour for servants, employs women and children and, finally exposes the corn to less risk of pilfering.

3199 *In the flail mode of threshing* the produce is constantly exposed to the depredations of the persons employed in executing the business which is a great objection and in many cases this mode proves a source of great loss to the farmer as he cannot by any means prevent the impositions to which it renders him liable. It has been observed by Middleton in his *Survey of Middlesex* that "where threshers are employed by the day they frequently do not perform half the work that ought to be done in the time, nor even that in a perfectly clean manner, and that if it be executed by the quarter or by the truss, the freest corn is threshed out, and the rest left in the ear." The same thing takes place in a greater or less degree in every other mode that can be devised for having the work performed by the hand, and it is consequently only by the general introduction and use of the threshing machine that the property and interest of the farmer can be fully secured and work be executed with a proper degree of economy.

3200. *In respect to the mode of threshing corn by the flail*, it is the practice in some districts for only one person to be employed upon a floor yet as two can thresh together with equal if not greater expedition and dispatch it must be a disadvantageous mode but where more than two labourers thresh together, which is sometimes the case there must be frequent interruptions, and a consequent loss of time. The flail or tool by which this sort of business is performed should be well adapted to the size and strength of the person who makes use of it, as when disproportionately heavy in that part which acts upon the grain it much sooner fatigues the labourer without any advantage being gained in the beating out of the grain. The best method of attaching the different parts of the implement together is probably by means of caps and thongs of good tough leather. Iron is however sometimes employed. In threshing most sorts of corn but particularly wheat, the operators should wear thin light shoes, in order to avoid bruising the grains as much as possible. In the execution of the work, when the corn is bound into sheaves it is usual for the threshers to begin at the ear ends, and proceed regularly to the others then turning the sheaves in a quick manner by means of the flail, to proceed in the same way with the other side, thus finishing the work.

3201. *The quantity of corn that a labourer will thresh with the flail* in any given period of time, must depend on the nature of the grain the freeness with which it threshes, and the exertions of the labourer in general it may be of wheat from one to one and a half quarter of barley from one and a half to two quarters, and of oats mostly about two in the day. The exertions of labourers in this sort of work in the northern districts of the kingdom are, however much greater than in those of the south, of course a much larger proportion of labour must be performed. In some places it is the practice to thresh by the measure of grain, as the bushel quarter &c. while in others it is done by the thrave of twenty-four sheaves, and in some by the day. In whatever way the agriculturist has this sort of business performed, there is always much necessity for his constant inspection in order to prevent the frauds and impositions that are too frequently practised upon him by the persons engaged in the execution of it.

3202. *The practice of whapping out grain* is resorted to in some districts with wheat, when the straw is much wanted for thatch. The operator takes a handful, and strikes the ears repeatedly against a stone, the edge of a board, or the face of a strong wattled hurdle, till the corn is separated.

3203. *Burning out* a mode formerly practised in the Highlands of Scotland, and not yet obsolete, may be noticed here. It is to burn the straw with the corn in it, instead of subjecting it to the flail. This has been described in several of the County Reports, particularly in *Walker's Hebrides* and *Macdonald's Report of the Western Islands*. The corn is thus not only separated from the straw but sufficiently dried or parched to grind without being sent to the kiln. It is a bad practice as the straw is lost, and consequently the soil, for want of manure, must soon become barren.

3204. *Repping* is the operation of separating the boles or seed-pods of flax and hemp by striking in the manner of whipping, or more commonly by drawing them through an implement of the comb kind, constructed with several upright triangular prongs set near together in a strong piece of wood.

3205. *Hedging and ditching* the operation of making and mending fences and open water-courses of the different kinds already enumerated, consists of the combined application of digging, shovelling, cutting, clipping, and faggoting, described in this section and the two foregoing.

3206. *Faggoting* is a term applied to the dressing or binding of the prunings or superfluous branches and spray of hedges. The bundles are made of different sizes in different parts of the country and in the same place according to the purpose to which they are to be applied. They are tied with willow, hazel, or some other pliable wood, twisted before application.

3207. *Stacking wood for fuel* occurs in the practice of common agriculture when hedges and pollard trees or tree-roots are stocked or dug up. The wood, whether roots or trunk, is cut into lengths of from eighteen inches to two feet with a saw then split with iron wedges into pieces of not more than an inch and a half or two inches in diameter, and built into an oblong stack generally three feet broad and high, and six feet long.

3208. *Stacking wood for burning, stowing for tar or pyroligneous acid, charring, and similar purposes*, are peculiar to forest culture, and will be treated of in the proper place (See Part III. or Index.)

3209. *Paring and burning* is the process of paring off the surface of lands in a state of grass, in order to prepare them for arable culture by means of fire. In the method of performing the process there is some slight difference in different districts, and an attention to the nature of the lands is as necessary as in other husbandry operations. It would seem that some soils, as those of the more clayey and heavy kinds would be most benefited by having the fire as much as possible in contact with the whole of their superficial parts, without being carried too far as by that means they may be rendered more proper for the reception of the roots of vegetables after being slightly ploughed, as well as more suitable for supplying nourishment to them while in others, as those of the more light and thin description, it might be most advantageous merely to consume the thin paring of sward after being piled up for the purpose without permitting the fire to exert its influence upon the mould or soil immediately below as in this way there would not probably be so much danger of injuring the staple by destroying the vegetable matters contained in such soils. Of course, in the first of these modes of burning the sward, the sods or parings should be piled up as little as possible into heaps, the advantage of a suitable season being taken to apply the fire to them in the state in which they lie or are set at first after being cut up or after a few only have been placed together as in some instances where they are, immediately after being cut, set on edge to dry and placed in serpentine directions in order to prevent them from falling over. In the latter cases they should be formed or built up into little circular heaps or piles, somewhat in the form and size of the little cocks made in hay-fields, the sods being placed the grass-side downwards, in order to admit air but the openings both at the bottoms and tops, after they have been fully set on fire by some combustible substance, such as straw &c. are to be closed up and those in other parts covered by an addition of sods, so that the combustion may proceed in a slow smothering manner as practised in the making of charcoal. When the whole of the earth in each of the piles has been acted upon by the fire, the heaps may be suffered to extinguish themselves by slowly burning out.

3210. *A variety of the operation, called skiving or peat-burning* is practised in Devonshire and Cornwall, for breaking up and preparing grass lands for the reception of fallow crops. A part of the sward or surface is alternately left unturnd, upon which the next thin furrow slice is constantly turned so that the wards of each come in contact, by which means the putrefactive fermentation is speedily excited and the greatest part of the grassy vegetable matter converted into manure. What ultimately remains undestroyed being, after repeated cross-cuttings with the plough and harrowings collected into small heaps and burnt, the ashes are then spread evenly over the land.

3211. With respect to the *implements used in paring*, different kinds are made use of in different parts of the island that which was the most employed in the misney of the art, was a kind of curved mattock or adze, about seven or eight inches in length, and five or six in breadth, and which, from its shape would appear to have been better adapted for cutting up the roots of brushwood, furze, broom, or other coarse shrubs, than for paring off the surface of a field free from such incumbrances. Where the soil is pared off by manual labour the ordinary breast-spade, in some places called the breast-plough and in Scotland the slaughter-spade, is mostly employed. In working the tool the labourer generally cuts the sods at about an inch or an inch and a half thick, and from ten to twelve inches broad and when the spade has run under the sod to the length of about three feet, he throws it off, by turning the instrument to one side, and proceeds in the same way cutting and throwing over the sods, the whole length of the ridge. In this way of performing the operation, the labourers by following each other with a slice of the sward or surface of the land, accomplish the business with much ease and in an expeditious manner.

3212. In the *heavy districts*, on the eastern coast, where paring and burning is practised on a large scale the horse paring plough is used, made of different constructions, according to the circumstances of the ground to be pared. These ploughs are calculated for paring off the sward or sod of such grounds as are level, and where neither stones, brush-wood ant-hills, nor other impediments obstruct their

progress; but where such obstacles present themselves, the breast-spike, or the common team-plough with a small alteration of the share, will be found preferable, both in respect to the extent of ground that can be pared, and the superior manner in which the work in such cases can be performed. Floughs, from their great expedition and regularity of performing the business, should always be made use of where the nature and situation of the land will admit them, in preference to such tools as require manual labour.

3215. In some of the western counties, the common plough only is used. There the wild grass fields, when it is proposed to burn the swards, are rib or slob furrowed about the beginning of winter and being again cross-ploughed the following spring, the sods are collected and macerated in the manner mentioned in speaking of skirling. In those cases, the plough has, however, a wing turned up on the furrow side of the ploughshare, by which the furrow is cut any breadth required.

3216. The season for paring and burning is in April, May and June the particular period must, however, always depend much on the state of the weather and the nature of the crop. When the east winds prevail, in February and March this sort of business may sometimes be carried on. But for accomplishing the work with the greatest dispatch and also with the least trouble and expense, a dry season is obviously the best. The prudent cultivator should not embark in the undertaking, unless there is a reasonable probability of his accomplishing it while the weather keeps dry and favourable. In the more northern districts, the latter end of May or the beginning of June, when the hurry of the spring seed-time is over and a number of hands can be most easily procured may, upon the whole, be considered the best and most convenient season as at this period the green vegetable products are in their most succulent state, and of course may probably afford more saline matter but, in the more southern counties, either a much earlier season must be taken, or the interval between the hay season and the harvest time must be fixed upon; the latter of which is, on the principle just stated, evidently the best, where the extent of ground to be burnt is not too large. In other seasons it would frequently be impossible to procure a sufficient number of hands for performing the business. In bringing waste lands into cultivation where an extensive tract of ground is to undergo this process, the autumn may in many cases, afford a convenient opportunity for the operation. A good deal depends on the crops that are to be sown after paring and burning. When rape or turnips are to be cultivated the end of May or the beginning of June will be the most proper time; but if barley or oats are to be sown the paring and burning must be completed as early in spring as the nature of the season will admit and when lands are pared and burned as a preparation for a crop of wheat, July, or even the beginning of August, may in favourable seasons, answer, but it is better to have the ground ready sooner if possible.

3217. In respect to the depth to which lands of different qualities may be pared with the most advantage, it is obvious that as it can hardly be proper to pare light thin stapled soils to the same depth as those of the more deep and heavy kinds, it should, in some degree, be regulated by their particular nature, and their difference in depth and heaviness. Boys who is in the habit of breaking up thin chalky soils, and such as have been in tillage in this way, observes, that in Kent, where the method of paring most in use is with down-spike or breast-ploughs, they take off turf as thick as the nature of the soil will admit from half an inch to two inches the thicker the better provided there is a sufficient portion of vegetable matter contained within them to make them burn well. The most usual depths of paring are from about one inch to three.

3218. In regard to burning when the season is not very wet, the turves will commonly be sufficiently dried in about a fortnight or three weeks, even without being turned, but in rainy weather they require a longer time and must be turned more than once to prevent their sticking out roots and shoots, which might hinder them from burning.

3217. Spreading the ashes. As soon as the turves have fully undergone the process of burning, and are reduced to the state of ashes and a powdery earthy matter the whole should, as soon as possible, be spread out over the land in as regular and equal a manner as the nature of the work will admit of, for without great attention in this respect, great inequality in the crops may take place besides, the soil will be made lighter in some places than in others which may be disadvantageous in the same way. The spreading where it can by any means be accomplished should always be performed before any rain falls; as where this point is not attended to, a great loss may be sustained by the saline matters being carried down in a state of solution and their beneficial effects in a great measure lost before the crops are in a condition to receive them. In order to secure the full influence of the ashes, the land is frequently slightly ploughed over immediately after the ashes are spread out, and it is stated by Donaldson that those who are more than ordinarily attentive in this respect, only rib or slob furrow the field so that the ashes after burning may be covered up with the greater expedition and dispatch. By this mode however they probably cannot be so equally mixed with the soil as by that of ploughing the whole field with a very slob furrow so as just to cover them.

3218. The expense of the operation of paring and burning will vary according to the nature and situation of the land, the method in which it is performed, and the customs of the district in regard to the price of labour. On the thin sort of chalky soils it is stated by Boys, that the expense for paring at a moderate thickness, where the land is not very stony is about equal to four or five ploughings.

3219. The operation of drying and burning clay for manure is in several respects similar to that of paring and burning the verdant surface. The practice of burning clay has at various times been pursued with energy and success, and at other times has fallen into neglect. The oldest book in which it is mentioned, is probably *The Country Gentleman's Companion*, by Stephen Switzer Gardener London, 1732. In that work it is stated that the Earl of Halifax was the inventor of this useful improvement and that it was much practised in Sussex. There are engravings of two kilns for burning clay one adopted in England, and the other in Scotland where it is said to have been ascertained that lands reduced by tillage to poverty would produce an excellent crop of turnips, if the ground were ploughed two or three times, and clay ashes spread over it. In the same work, there are several letters written in the years 1730 and 1731, stating that the plan of burning clay had answered in several parts of England and accounts were received from Scotland, that upon experiment it had answered better than either lime or dung, but was found too expensive. The practice is described at length in Ellis's *Practical Farmer, or Hertfordshire Husbandman* 1782. In 1786, James Arbuthnot of Peterhead tried several successful experiments with burning clay and various others have since been made in different parts of the empire. In 1814 the practice was revived and written on by Craig of Cally near Dumfries, and soon after by General Beatson near Tunbridge by Curgen, Burrows, and several correspondents of agricultural journals. In Ireland, it would appear the practice prevails in several places, and Craig says he adopted it from seeing its effects there. The result of the whole is, that the benefits of this mode of manuring have been greatly exaggerated;

though they certainly appear to be considerable on clayey soils. Aiton (*Farmer's Mag.* vol. xxi. p. 493) compares this rage for burning clay which existed in 1815, to the form mania of a few years prior date. In 1822, he found few of the advocates for these improvements disposed to say much on the subject, and saw very few clay kilns smoking. "To give my ultimatum upon this subject," he says, "I regret that the discoverers of foin grass, and of the effects of burnt clay have so far overrated their value. Both are useful and proper to be attended to—the grass to be raised on patches of marshy ground, and used as green food to cattle in winter and the burnt earth as a corrector of the mechanical arrangement of a stubborn clay soil and I have no doubt, but if they had been only recommended for those valuable purposes, they would have been brought into more general use than they yet are, or will be till the prejudices against them, arising from the disappointment of expectations raised high by too flattering descriptions, are removed.

5220. The action of burnt clay on the soil is thus described by the same author—"It must be obvious to every person who has paid attention to the subject, that when clay or other earth is burnt into ashes like brick-dust, it will not (unless sands are applied to it) return again to its former state of clay but will remain in the granulated state of ashes or friable mould to which it was reduced by the operation of burning. An admixture of that kind with a strong adhesive clay must evidently operate as a powerful manure, by changing the mechanical arrangement of the latter and rendering it more friable giving greater facility to the percolation of redundant moisture and to the spreading of the roots of vegetables in quest of food. The application of as much water sand, or any similar substance would have exactly the same effect. In opening and keeping open the pores of an adhesive clay soil, and converting it into the quality of loam. Besides this which would be a permanent improvement upon the staple or texture of every clay soil, burnt clay or torrefied earth may sometimes acquire, in that operation a small quantity of soot or carbonic matter that may in favourable circumstances, operate for one season as a manure, or as a stimulus, to a small extent, to the growth of vegetables. This at least may be the case, if the clay or earth burnt shall abound with vegetable matter and if the burning is conducted in such a smothered way as to prevent the smoke or vegetable matter from escaping. But as it is the subsoil that is recommended, and seems to be generally used for burning it is impossible any considerable quantity of vegetable matter can be found in it.

5221. The calcareous matter in the soil, it is said, will be calcined and formed into lime by the operation of burning; but I am disposed to consider this argument as far more plausible than solid. Calcareous matter is no doubt found, on chemical analysis, to a certain extent in some soils perhaps some perceptible portion of it may be found in every soil but it is seldom or never found in any soil, to such an extent as to be of much use as a manure to other land. Even where the soil is impregnated with a large portion of calcareous matter if it is not in the form of limestone, but minutely mixed with it the burning cannot either increase or much alter the lime if it is in the form of stones however small, or in what is called limestone gravel, there is little chance of its being calcined in the operation of burning the clay, it would go through that ordeal unaltered. Any change, therefore that can be made upon the small portion of calcareous matter in the soil by burning in the manner directed can scarcely have any perceptible effect, when that matter is applied as manure to other soils. And though it is possible that some qualities in particular soils unfavourable to vegetation, may be corrected by burning, and that in some other instances the fire may render the clay more nutritive to plants (though I have not been able to trace this, or even to conjecture how it can happen) yet I am much disposed to believe, that its effect as a mechanical mixture in opening the pores of the soil, is the chief improvement that can be derived from the application of burnt clay as a manure. If it has any other effect it must be from the soot or carbonic matter collected during the operation of burning or perhaps it may acquire, by the torrefaction, something of a stimulating quality that may for a short time promote the growth of particular plants but these qualities can only be to a small extent, and continue to act for a very limited period. (*Farmer's Mag.* xxi. 493.)

5222. The action of burnt clay according to a writer in *The Farmer's Journal*, is at least three-fold, and may be manifold. It opens the texture of stubborn clays, gives a drain to the water spiracles to the air and affords to the roots facility of penetrating. Clay ashes burnt from turves, containing an admixture of vegetable matter consist, in some small proportion, of vegetable alkali or potash, a salt which is known to be a good manure. It also, in most cases happens that a stiff cold clay is impregnated with pyrites a compound of sulphuric acid and iron. Although the chemical attraction between these two bodies is so strong, that it is one of the most difficult operations in the arts totally to free iron from sulphur yet a very moderate heat sublimates a large portion of the sulphur. The iron is then left at liberty to re-absorb a portion of the redundant sulphuric acid, which too generally is found in these soils, and thereby sweetens the land and it is probable that the bright red or crimson calx of iron, which gives colouring to the ashes when over-burnt, is beneficial to vegetation in the present case inasmuch as it is of itself, one of the happiest aids to fertility as exemplified in the red marl strata and red sand strata throughout the kingdom. The evolution and recombination of different gases, no doubt, materially affect the question but it is reserved for accurate chemical observers to give us an account of the processes which take place in this respect. Curwen notices that clay ashes do no benefit as a top-dressing on grass, which is in part to be explained by reason that the ashes, when spread on the surface of the grass, cannot exert mechanical action on the soil in the ways enumerated. Neither can the calx of iron come so immediately in contact with the particles of the soil, for the production of any chemical effect, as it would do if the ashes were ploughed in. In short, like many other manures which are laid on the surface unless it contains something soluble which may be washed into the ground by rains it does very little good; and the feeble proportion of vegetable alkali is probably the only soluble matter the ashes contain. However sanguine may be the admirers of burnt clay all experience confirms that the most beneficial clay ashes are those which are burnt from the greatest proportion of rich old turf ancient banks, roots of bushes, and other vegetable matters and, I conceive, the value of mere powdered pottery (for such it is) may easily be overrated. (*Farmer's Journal*, 1812.)

5223. The common method of burning clay is to make an oblong enclosure, of the dimensions of a small house (say 15 feet by 10) of green turf sods, raised to the height of 3½ or 4 feet. In the inside of this enclosure, air-pipes are drawn diagonally which communicate with holes left at each corner of the exterior wall. These pipes are formed of sods put on edge and the space between these as wide only as another sod can easily cover. In each of the four spaces left between the air-pipes and the outer wall a fire is kindled with wood and dry turf, and then the whole of the inside of the enclosure or kiln filled with dry turf which is very soon on fire, and on the top of that, when well kindled is thrown the clay, in small quantities at a time, and repeated as often as neces-

ary, which must be regulated by the intensity of the burning. The air pipes are of use only at first, because, if the fire burn with tolerable keenness, the sods forming the pipes will soon be reduced to ashes. The pipe on the weather side of the kiln only is left open, the mouths of the other three being stopped up and not opened except the wind should veer about. As the inside of the enclosure or kiln begins to be filled up with clay, the outer wall must be raised in height, always taking care to have it at least fifteen inches higher than the top of the clay for the purpose of keeping the wind from acting on the fire. When the fire burns through the outer wall, which it often does, and particularly when the top is overloaded with clay the breach must be stopped up immediately, which can only be effectually done by building another sod wall from the foundation, opposite to it, and the sods that formed that part of the first wall are soon reduced to ashes. The wall can be raised as high as may be convenient to throw on the clay and the kiln may be increased to any size, by forming a new wall when the previous one is burnt through.

3224. *The principal art in burning consists in having the outer wall made quite close and impervious to the external air and taking care to have the top always lightly but completely covered with clay, because if the external air should come in contact with the fire either on the top of the kiln, or by means of its bursting through the sides, the fire will be very soon extinguished. In short, the kilns require to be attended nearly as closely as charcoal pits. Clay is much more easily burnt than either moss or loam — it does not undergo any alteration in its shape, and on that account allows the fire and smoke to get up easily between the lumps whereas moss and loam by crumpling down are very apt to smother the fire unless carefully attended to. No rule can be laid down for regulating the size of the lumps of clay thrown on the kiln as that must depend on the state of the fire but every lump has been found completely burnt on open grates when some of them were thrown on larger than my head. Clay, no doubt, burns more readily if it be dug up and dried for a day or two before it be thrown on the kiln but this operation is not necessary as it will burn though thrown on quite wet. After a kiln is fairly set a going no coal or wood or any sort of combustible is necessary the wet clay burning of itself and it can only be extinguished by intention, or the carelessness of the operator — the vicissitudes of the weather having hardly any effect on the fire, if properly attended to. It may perhaps be necessary to mention that when the kiln is burning with great keenness, a stranger to the operation may be apt to think that the fire is extinguished. If, therefore, any person, either through impatience, or too great curiosity should in so looking into the interior of the kiln, he will certainly retard, and may possibly extinguish the fire, for as before mentioned, the chief art consists in keeping out the external air from the fire. Where there is abundance of clay and no great quantity of green turf it would, perhaps, be best to burn the clay in draw kilns, the reverse as lime.*

3225. *An improved method of burning clay has been adopted by Colonel Dickson at Hexham and by the gentlemen in Northumberland. Instead of building a kiln gratings or arches of cast iron are used to form a vault or funnel for the fuel, and over the funnel the clay is built.*

The grates are made about two feet and a half long, two feet diameter and about fourteen inches high. One grating is to be filled with brushwood stubble or any other cheap fuel and the clay as it is dug built upon it to a convenient height leaving small canals, or boring holes to allow the heat to penetrate to the middle and outer parts of the clay. When a sufficient quantity is built upon the first grating another is added at either end, or at both filled with similar fuel, and the clay built upon them as before. If a process is continued until 16, 12, or a greater number of the gratings have been used, when one end is built up or covered with clay and at the other, under the last grating, a fire is made of coals or faggot wood. The end at which the fire is made should face the wind if possible, and if the process has been properly conducted the clay will be effectually burnt. By commencing with a centre grating in the form of a cross (fig. 517), the workman may build from four ends in the place of two, this contrivance will afford a facility in the work, and have a draft of wind at two entrances.

3226. *The advantage of this mode of burning clay is the saving of cartage, as the clay may be always burned where it is dug.*  
 3227. *Burning clay and surface soil by lime without fuel, has been practised by Curwen (Farm Magazine xvi. p. 11, 12) in the following manner. — Mounds of seven yards in length and three and a half in breadth, are loaded with seventy two Winchester bushels of lime. First, a layer of dry sods or parings, on which a quantity of lime is spread, mixing soda with it, then a covering of eight inches of soda, on which the other half of the lime is spread and covered a foot thick. The height of the mound being about a yard. In twenty four hours it will take fire. The lime should be immediately from the kiln. It is better to suffer it to ignite itself than to effect it by the operation of water. When the fire is fairly kindled, fresh soda must be applied. Mr Curwen recommends obtaining a sufficient body of ashes before any clay is put on the mounds. The fire naturally rises to the top. It takes less time and does more work, to draw down the ashes from the top, and not to suffer it to rise above six feet. The former practice of burning in kilns was more expensive did much less work, and, in many instances, calcined the ashes and rendered them of no value.*

3228. *Use of pyrites in burning clay. A writer in The Farmer's Journal (Dec 1821) asserts that "the greater part of many beds of cold clay contain in them a substance, or ingredient, which is in itself, to a great degree, combustible, as known to every brick-burner. This probably is in most cases, the sulphur of the pyrites contained in the clay but be it what it may it prevails to such a degree that a very small quantity of fuel is sufficient to burn a very large body of clay. It is only requisite to have sufficient fuel to set fire to the heap at first, so as to raise a body of heat, and, for the rest the clay will nearly burn of itself being judiciously arranged round and upon the burning centre. The ashes are in the best state when they have been exposed only to a moderate heat namely to a heat not only far below what will produce vitrification but even so low as not to produce a permanent red colour the black ashes, or dry red and brownish red, being made superior in value to bright red ashes, that is, to well burnt bricks. The heat is moderated chiefly, by the judicious application of the crumbs and moulding fragments of clay or coal so as to prevent the draft of the air through the apertures between the large clods or tufts from being too free. A very small admixture of vegetable fuel suffices to keep up the fire.*

3229. *The application of burnt clay as a manure is the same as that of lime. It is spread over fallows or lands in preparation for turneps, at the rate of from thirty to fifty loads or upwards per acre. A few years ago this practice made considerable noise, but at present it has fallen into disrepute.*

3230. *The general manual operations common to British agriculture being now described, a variety of operations peculiar to particular departments, such as boring for water, puddling to retain water building drains, &c. which belong to draining and harking timber burning charcoal, distilling pyroligneous acid, which belong to planting; will be found under these departments.*

## CHAP. II.

### *Agricultural Operations requiring the Aid of Labouring Cattle.*

3231 *Operations requiring the aid of labouring cattle are in a peculiar manner entitled to the appellation of agricultural. Almost all the operations described in the former chapter may be performed by common country labourers but those we are now to enter on, are exclusively performed by farm servants. They may be classed as operations for the use and management of live stock labours on the soil, and compound operations.*

#### *SECT. I Operations for the Care of Live Stock*

3232. *Herding or tending of cattle, as an operation is the simplest which is connected with domestic animals. It consists in conducting them to a certain pasturage keeping them within the prescribed limits preventing them from injuring one another observing if any are diseased, and the like. It is commonly performed with the aid of the dog, and by boys or girls for a small herd or flock, and aged or elderly men for larger herds. In modern times, the place of the cow and cattle herd is generally supplied by fences but where large flocks of sheep are kept, it is still necessary to have a shepherd not in many cases, so much to keep the flock together and in its proper place, as to watch the progress of their growth the approaches of disease, parturition &c. In almost all cases, mild and gentle treatment ought to be made the *ans quid non* of the herdsman's conduct. The duties of the shepherd, who has the general care of either a flock or herd, are various and important, and, to be duly executed, imply no inconsiderable degree of physiological and veterinary knowledge. See Part III Book VII *The Economy of Live Stock**

3233. *Cleaning cattle is the operation of rubbing, brushing, combing and washing their bodies, and picking their feet. The legs of cattle when soiled by labour are commonly washed by walking them two or three times through a pond, formed on purpose in or near to farmyards. As soon as they are put in the stable and unharnessed, the legs, and such parts as are wetted, should be powerfully rubbed with dry straw so as to dry the hair and the same process should be applied to the rest of the body if they have been in a state of copious perspiration. At the same time their feet should be picked, and their hoofs freed from any earth or small stones which may have lodged under the shoe, or in the case of labouring oxen between the hoofs. Combing and brushing can only be performed when the hair and skin are perfectly dry and in farmyards is generally done in the morning when they are first fed and in the evening when last fed. In general, it may be considered as experimentally decided, that cleaning cattle of every description cows and oxen as well as horses, contributes much to their health as well as to their beauty. If swine were cleaned as regularly as horses, there can be no doubt they would be equally benefited by it. Some amateurs have their feeding swine regularly cleaned but the greater part of professional agriculturists content themselves with fixing one or more rubbing posts in each sty, with frequent renewing of the litter*

3234. *Feeding, or supplying food to cattle is an operation which, like every other however simple or humble, requires attention and a principle of action. Food ought to be given at stated times, in such quantities as to satisfy but not to glut the animals, and varied in quality so as to keep appetite alive. Water ought to be regularly supplied according to the kind of food, the state of the animal and the season of the year. Cattle, that are fed in part on green food or roots, will require less water than those fed on dry hay straw, or corn and cattle that have been at work and perspiring will require more water than such as have been idle or at pasture. In summer cattle fed on dry food obviously require more water than in winter owing to the increased perspiration. The case of sick animals must be regulated by the nature of their disease, or directed by the veterinary surgeon. In treating of agricultural animals (Part III.) we shall give the diseases, and treatment of each.*

3235. *The harnessing of cattle requires attention, first, that the harness be in complete order and, secondly that it fit the parts of the animal to which it is applied. Collars and saddles are the leading articles, and when they gall or in any way incommode the animal, they are ruinous to his comfort, and soon render him unfit for labour. Even when they fit properly, an improper mode of fixing the collar-blades (hames), and tying the girth of the saddle, may greatly annoy the animal, and render him restive during the whole period he is in yoke*

3256. *The yoking of draught animals* requires still more attention than harnessing them. To know when an animal is properly yoked, or placed in proper circumstances to perform the kind of labour assigned to him, it is necessary to have clear ideas as to the kind of power to be exerted by the animal, whether drawing, carrying, pushing, or two or all of these. The horse and ox draw from their shoulders, carry from their back, and push with their breech. The point of resistance in all weights, or objects to be dragged or pushed along the ground's surface, lies below the centre of gravity, and in all cases of drawing, a line from this point of resistance to the collar of the animal should form a right angle with the plane of the collar-bone. Hence the necessity of allowing the plough chains from the back of the animal to hang freely, so as to form a straight line from the collar-blades through the muzzle of the plough to the point of resistance. Hence, also, the advantage of yoking two horses in a cart by means of the endless rope or chain already described. (3755.) In yoking animals where the labour is principally carrying a weight, as in carting, great care is requisite that the weight be not oppressive, and that the suspending chain move freely in the groove of the saddle, so as to produce a perfect equipoise. Various opinions are entertained as to the weight which a horse can carry with or without drawing at the same time. According to the practice of experienced carters, if a one horse cart is loaded with 20 cwt. 5 cwt., but not more, may be allowed to rest on the back of the horse by means of the traces chain, and saddle. This is meant to apply where the roads are level in going up or down hill, to admit of the same proportion of weight, the traces, or shafts, or the bearing chain, must be lowered or raised according to circumstances. Yoking animals to push only is a case that seldom or never occurs, but it will be useful to mention, that, as the line of the breech of animals is nearly perpendicular to the horizon, and the principle being that the line of exertion should be at right angles to the exerting surface, so the direction of pushing or backing, as it is commonly called, may be a horizontal line, or a line parallel to the surface on which the animal stands.

3257. *The hours of consecutive labour to which animals are subjected* form a matter which deserves consideration. The advantage of short stages in drawing heavy loads has been proved by Mr Stuart Menteth of Closeburn, this gentleman, who is proprietor of one of the richest coal fields in the island, both as to quantity and quality has very successfully employed horse power to the drawing of heavy loads, by dividing the roads into short stages. Before this expedient was resorted to, each horse could travel the distance of only 18 miles, and return with a load of 24 cwt. thrice a week that is to say the aggregate of the labour of each horse amounted to 9 tons 2 cwt. weekly but by dividing that distance into 4 stages of  $4\frac{1}{2}$  miles each, 4 horses can make 3 trips daily and draw a load of 59 cwt. each trip, or very nearly 5 tons daily, or 30 tons weekly. Hence, according to this method, the aggregate of the labour of each horse amounts to about 7 tons weekly. Suppose 16 horses are employed instead of making them travel 18 miles one day and return with a load the following, the more advantageous plan is to arrange them in 4 divisions, and make each division travel only  $4\frac{1}{2}$  miles in succession, were this distance divided into six stages, the load might be proportionally increased, with less fatigue to the horses for it will invariably be found that the most profitable mode of applying the labour of horses, is to vary their muscular action, and revive its tone by short and frequent intervals of repose. Where stone rail-tracks laid down on the *pulleys* between Sheriff Hall and Edinburgh, and the above plan adopted with waggons not exceeding 11 cwt. similar to those used by Mr Stuart Menteth the inhabitants might be supplied with coal at a cheaper rate than by any other existing mode of conveyance. Mr Stuart Menteth considers the same principle equally applicable to ploughing instead of 3 yokings, as at present, of 4 hours each, were 3 yokings of 24 hours each substituted, the horses would be less exhausted, and more work accomplished. (Scotsman, Jan. 6 1830.)

3258. *The labour of a horse in a day* according to Professor Leslie, is commonly reckoned equal to that of five men. but he works only 8 hours, while a man easily continues his exertions for 10 hours. Horses likewise display much greater force in carrying than in pulling, and yet an active walker will beat them on a long journey their power of traction seldom exceeds 144 lbs. but they are capable of carrying more than six times as much weight. The pack-horses in the West Riding of Yorkshire are accustomed to transport loads of 480 lb. over a hilly country, but in many parts of England, the milch-horses will carry the enormous burthen of 910 lbs. to a short distance. The action of a horse is greatly reduced by the duration of his task; though not numbered at all with any load or draught, he would be completely exhausted perhaps, by a continued motion for 20 hours in a day. Though a horse might start with a celerity of 16 miles, this would be reduced in 4 hours to 104 and in 8 hours to 52. Hence the great advantages resulting from short stages, lately adopted for the rapid conveyance of the mail. (Elements of Natural Philosophy.)

## SECT II Labours with Cattle on the Soil.

\*3259. *Ploughing* is justly considered the most important of agricultural operations, as on the manner in which this is performed depends the facility of executing all succeeding operations on the same piece of land. The plough acts as a wedge, separating a portion of the soil, and turning it over at the same time. If this wedge were properly constructed,

and if the soil presented everywhere the same resistance to it, it would require no holding, but would maintain its position when drawn along by the cattle, but as the least inequality of surface or tenacity or the additional resistance of a root or stone, destroys the equilibrium of the forces acting against the wedge, the presence of the holder or ploughman becomes necessary to adjust its position. In two-wheeled ploughs, however, this is done in a great measure by the wheels, but not so rapidly as by the instantaneous movement of the holder on the ends of the handles acting as levers. The manual operation of holding the plough in a proper position, and directing the horses or cattle which draw it at the same time, is only to be acquired by experience when once attained it is perhaps the most agreeable and healthy of agricultural exercises, the body being kept upright, the arms and legs brought into action and also the eye and the mind, to keep the furrow straight and of regular width and depth, and the voice to speak to the horses. It is almost needless to mention that the art of drawing a straight furrow with a plough in which the horses are yoked in pairs, consists in keeping each of the horses a small distance apart, so as to see forward between them and next to fix the eye on two or more objects beyond the land to be ploughed, and keep these objects and the coulter or mould of the plough always in one line. By far the best practical directions for ploughing have been given by the author of the article *Agriculture* in the Supplement to the *Encyclopædia Brit* which we shall quote at length.

3340. *Three different points require particular attention in ploughing* 1. The breadth of the slice to be cut. 2. Its depth. and 3. the degree in which it is to be turned over. — which last circumstance depends both upon the construction of the plough particularly the mould-board, and the care of the ploughman.

3341. *The breadth and depth of the furrow-slice* are regulated by judiciously placing the draught on the nose or bridle of the plough setting it so as to go more or less deep, and to take more or less land or breadth of slice, according as may be desired. In general the plough is so regulated that, if left to itself, and merely kept from falling over it would cut a little broader and a little deeper than is required. The coulter is also placed with some inclination towards the left or land side, and the point of the sock or share has a slight tendency downwards.

3342. *The degree to which the furrow-slice turns over* is in a great measure determined by the proportion between its breadth and depth which for general purposes is usually as three is to two or when the furrow is nine inches broad, it ought to be six inches in depth. When the slice is cut in this proportion, it will be nearly half turned over or recline at an angle of forty or forty five degrees; and a field so ploughed will have its ridges longitudinally ribbed into angular drills or ridgelets. But if the slice is much broader in proportion to its depth it will be almost completely overturned or left nearly flat, with its original surface downwards, and each successive slice will be somewhat overlapped by that which was turned over immediately before it. And finally, when the depth materially exceeds the width each furrow-slice will fall over on its side, leaving all the original surface bare, and only laid somewhat obliquely to the horizon.

3343. *Ploughing with the breadth and depth nearly in the proportion of three to two* is best adapted for laying up stubble land after harvest, when it is to remain during winter exposed to the mellowing influence of frost, preparatory to fallow or turnips.

3344. *The shallow furrows of comestriculture* which are five inches in depth by eight or nine wide is under stood to answer best for breaking up old leys because it covers up the grass turf, and does not bury the manured soil.

3345. *Ploughing with the depth of the furrow considerably exceeding the width* is a most unprofitable and uneconomical operation, which ought seldom or never to be adopted.

3346. *The most generally useful breadth of a furrow-slice* is from eight to ten inches, and the depth which ought to be seldom less than four inches, cannot often exceed 14 or eight inches, except in soils uncommonly thick and fertile. When it is necessary to go deeper as for carrots and some other deep rooted plants, a trench ploughing may be given by means of a second plough following in the same furrow.

3347. *Shallow ploughing* ought always to be adopted after turnips are eaten on the ground, that the manure may not be buried too deep and also in covering lime, especially if the ground has been pulverised by following because it naturally tends to sink in the soil. In ploughing down farm-yard dung it is commonly necessary to go rather deep, that no part of the manure may be left exposed to the atmosphere. In the first ploughing for fallows or green crops, it is advisable to work as deep as possible; and no great danger is to be apprehended, though a small portion of the subsoil be at that time brought to the surface.

3348. *The furrow-slices are generally distributed into beds* varying in breadth according to circumstances, these are called *ridges or lands*, and are divided from one another by gutters or open furrows. These last serve as guides to the hand and eye of the sower, to the reaper, and also for the application of manures in a regular manner. In soils of a strong or retentive nature, or which have wet close subsoils, these furrows serve likewise as drains for carrying off the surface water and being cleared out, after the land is sown and harrowed have the name of *under furrows*. In wet lands, furrows are sometimes drawn or dug across the ridges, for the purpose of carrying off the surface water from hollows these are called *cross under furrows*.

3349. *Ridges* are not only different in breadth but are raised more or less in the middle on different soils. On clayey retentive soils, the great point to be attended to is the discharge of superfluous water. But narrow ridges or *strikes* of from three to five feet, are not approved of in some of the best cultivated countries. In these a breadth of fifteen or eighteen feet, the land raised by two gatherings of the plough is most commonly adopted for such soils; such ridges being thought more convenient for manuring, sowing, harrowing, and reaping, than narrower ones and the water is drained off quite as effectually.

3350. *Ridges on dry porous turnip soils* may be formed much broader and were it not for their use in directing the labourers, may be and sometimes are dispensed with altogether. They are often thirty or thirty-six feet broad, which in Scotland are called *head-ways* ridges, because reaped by a band of sheaves, commonly six, served by one binder. If it be wished to obliterate the intermediate furrows, this may be done by cutting up a narrow ridgelet or single bout-drill between the broad ridges, which is afterwards levelled by the harrow.

3351. *The mode of forming ridges straight and of uniform breadth* is as follows. — Let us suppose a field perfectly level, that is intended to be laid off into ridges of any determinable breadth. The best ploughman belonging to the farm conducts the operation, with the aid of three or more poles shod with iron in the following manner. The first thing is to mark off the head ridges, on which the horses turn in ploughing, which should in general be of an equal breadth from the bounding lines of the field. If these lines are not very crooked or irregular. The next operation, measuring one straight side of the field, or a line that has been made straight, as the proper direction of the ridges, is to measure off from it with one of the poles (all of them of a certain length, or expressing specific measures) half the intended breadth of the ridge if it is to be gathered or one breadth and a half if to be ploughed flat, and there the ploughman sets up a pole as a direction for the plough to enter. On a line with this, and at some distance, he plants a second pole, and then in the same manner a third, fourth &c. as the irregularity of the surface may

render necessary, though three must always be employed, — the last of them at the end of the intended ridge, and the whole in one straight line. He then enters the plough at the first pole, keeping the line of poles exactly between his horses, and ploughs down all the poles successively halting his horses at each, and replacing it at so many feet distant as the ridges are to be broad, so that when he reaches the end of the ridge, all his poles are again set up in a new line parallel to the first. He returns, however, along his former track, correcting any deviations, and throwing a shallow furrow on the side opposite to his former one. These furrows, when reversed form the crown of the ridge, and direct the ploughmen who are to follow. The same operations are carried on until the whole field is marked out. This is called *feiring* in Scotland and *striking or drawing out the furrows* in England. It is surprising with what accuracy these lines are drawn by skilful ploughmen.

322. Another method has been adopted for the same purpose, which promises to be useful with less experienced workmen. A stout lath or pole, exactly equal in length to the breadth of the intended ridge, is fixed to the plough at right angles to the line of the draught, one end of which is placed across the handles exactly opposite the coulter while the other end projects towards the left hand of the ploughman, and is preserved in its place by a rope passing from it to the collar of the near side horse. At the outer end of the lath, a coulter or harrow tine is fixed perpendicularly which makes a trace or mark on the ground as the plough moves onwards, exactly parallel to the line of draught. By this device, when the plough is *feiring* the crown of one ridge the marker traces the line on which the next ridge is to be *feired*. (*General Report of Scotland*, vol. i p. 304.)

323. The direction and length of ridges are points which must evidently be regulated by the nature of the surface and the size of the field. Short angular ridges called *batts* or *short work*, which are often necessary in a field with irregular boundaries, are always attended with a considerable loss of time, and ought to be avoided as much as possible.

324. In ploughing steep land it is advisable to give the ridges an inclination towards the right hand at the top, by which in going up the acclivity the furrow falls more readily from the plough, and with less fatigue to the horses. Another advantage of forming ridges in a slanting direction on such land is, that the soil is not so apt to be washed down from the higher ground, as if the ridges were laid at right angles. Wherever circumstances will permit, the best direction, however is due north and south by which the grain on both sides of the ridge enjoys nearly equal advantages from the influence of the sun.

325. *Bibbing* a kind of imperfect ploughing was formerly common on land intended for barley and was executed soon after harvest, as a preparation for the spring ploughing. A similar operation is still in use in some places, after land has been pulverised by clean ploughing, and is ready for receiving the seed. By this method only half the land is stirred, the furrow being laid over quite flat and covering an equal space of the level surface. But except in the latter instance, where corn is meant to grow in parallel lines, and where it is used as a substitute for a drill-machine, bibbing is highly objectionable and has become almost obsolete.

326. Land thus formed into ridges is afterwards cultivated without marking out the ridges anew, until the inter furrows have been obliterated by a fallow or fallow crop. This is done by one or other of the following modes of ploughing. — 1 If the soil be dry and the land has been ploughed flat, the ridges are split out in such a way that the space which the crown of the old ridge occupied is now allotted to the open furrow between the new ones. This is technically called *crown and furrow ploughing*. 2. When the soil is naturally rather wet, or if the ridges have been raised a little by former ploughings, the form of the old ridges, and the situation of the inter-furrows, are preserved by what is called *casting*, that is, the furrows of each ridge are all laid in one direction, while those of the next adjoining ridges are turned the contrary way two ridges being always ploughed together. 3 It is commonly necessary to raise the ridges on soils very tenacious of moisture, by what is called *gathering* which is done by the plough going round the ridge, beginning at the crown and raising all the furrow-slices inwards. 4 This last operation when it is wished to give the land a level surface, as in fallowing is reversed by turning all the furrow slices outwards beginning at the inter furrows, and leaving an open furrow on the crown of each ridge. In order to bring the land into as level a state as possible, the same mode of ploughing or casting, as it is called, may be repeated as often as necessary.

327 With respect to ploughing relatively to time in the strongest lands, a pair of good horses ought to plough three quarters of an acre in nine hours but upon the same land, after the first ploughing on friable soils, one acre or an acre and a quarter is a common day's work. Throughout the year an acre a day may be considered as a full average, on soils of a medium consistency. The whole series of furrows on an English statute acre, supposing each to be nine inches broad, would extend to 19 360 yards and adding 12 yards to every 220 for the ground travelled over in turning the whole work of an acre may be estimated at 20,416 yards, or 11 miles and nearly 5 furlongs.

328 In ploughing relatively to season it is well known that clayey or tenacious soils should never be ploughed when wet and that it is almost equally improper to allow them to become too dry especially if a crop is to be sown without a second ploughing. The state in which such lands should be ploughed is that which is commonly indicated by the phrase, 'between the wet and the dry,' — while the ground is slightly moist, mellow and the least cohesive.

329 The season best for ploughing the first time, for fallow or green crops, is immediately after harvest, or after wheat-sowing is finished and when this land has been gone over the old tough swards, if there be any are next turned up. The reasons for ploughing so early are sufficiently obvious as the frosts of winter render the soil more friable for the spring operations, and assist in destroying the weed roots. In some places, however the first ploughing for fallow is still delayed till after the spring seed-time. On extraordinary occasions land may be ploughed in the night as well as in the day by hanging lanterns to the horses collars. This it is said, is sometimes done in East Lothian, during a hurried seed-time (*Farm. Mag* vol. ix p. 55.)

3250. The *cultivator, grubber, scuffer, scarifiers*, and such like implements (2650.), are used to lessen the number of ploughings in fallows or light free soils. Their operation differs from that of the plough in not reversing the surface, and therefore they can never, as some have proposed, become a substitute for that implement in all cases. Still the grubber is a valuable implement. William Lester late of Northampton who is said first to have invented an implement of this kind, declares himself confident that one man a boy and six horses, will move as much land in a day and as effectually, as six ploughs, leaving land in a fallow state, that has been previously ploughed. We have elsewhere pointed out the mode of using this description of tillage implements (3650.), one great advantage of which is, that they may be used by the unskilful and even by operators who cannot guide a plough. As soon as steam shall be employed as a moving power in this department of agriculture, implements of this kind and especially Finlayson's harrow (3657) and Wilkie's brake (3656) will come into very general use.

3261 The operation of harrowing is intended both to drag out weeds and to cover the seeds when sown. It is obvious that implements of different sizes are not only necessary but even that these implements should be worked in different ways, according to the strength and condition of the soil on which they are employed, and the nature of the work to be executed. When employed to reduce a strong obdurate soil, not more than two of the old or common sort should be yoked together, because they are apt to ride and tumble upon each other and thus impede the work, and execute it imperfectly. It may also be remarked, that on rough soils harrows ought to be driven as fast as the horses can walk because their effect is in direct proportion to the degree of velocity with which they are driven. In ordinary cases, and in every case where harrowing is meant for covering the seeds, and the common implement in use, three harrows are the best yoke, because they fill up the ground more effectually and leave fewer vacancies,

than when a smaller number is employed the improved forms, calculated to cover the breadth of two or more of the old harrows by one frame (*fig* 518.), are only calculated for flat ridges, or for working dry lands in which ridging is not requisite.

3262. The harrow-man: at tention at the seed process, should be constantly directed to prevent these implements from riding upon each other and to keep them clear of every impediment, from stones, lumps of earth or clods, and quickens or grass roots for any of these prevent the implement from working

with perfection, and causes a mark or trail upon the surface, always unpleasant to the eye, and generally detrimental to the vegetation of the seed.

3263. Harrowing is usually given in different directions; first in length then across, and finally in length as at first. Careful agriculturists study in the finishing part of the process, to have the harrows drawn in a straight line without suffering the horses to go in a zigzag manner and are also attentive that the horses enter fairly upon the ridge, without making a curve at the outset. In some instances, an excess of harrowing has been found very prejudicial to the succeeding crop but it is always necessary to give so much as to break the furrow and level the surface, otherwise the operation is imperfectly performed.

3264 Horse-hoeing is the operation of stirring the ground between rows of vegetables, by means of implements of the hoe coulter or pronged kind, drawn by horses. Whoever can guide a plough, will find no difficulty in managing any implement used for stirring ground. The easiest kinds are those which have few hoes, or coulters or shares, and a wheel in front and the easiest circumstances, wide intervals between the rows, and a loose friable soil. Wherever soil is hard, rough, and rounded, as in the case of high-raised ridges, there should not be more than three prongs or shares in the implement, because more than three points can never touch a curved surface, and be in one plane; and if not in one plane, they will never work steadily, equally and agreeably.

3265 Turnip hoeing of every kind is accordingly exceedingly easy but stirring the earth between rows of beans on a strong clay soil in a time of drought, is proportionally difficult, and sometimes, when the ground rises in large lumps, dangerous for the plants. In stirring the soil between rows of beans, cabbages, or other plants, on strong or loamy

soils, a small plough often answers better than any of the pronged or coultered implements, at least for the first and last operations of bean culture. Dr Anderson, indeed, affirms with great truth, that nearly all the various operations of horse-hoeing may be executed by the common swing plough, in an equally effectual manner as by any of the hoe-ploughs usually made use of.

3266 *Drilling* or the deposition of seed in rows by means of a drill machine, is an operation that requires considerable care in the performance. The points that require particular attention are keeping the rows straight and at equal distances throughout their length, depositing the seed at a proper depth, and delivering the seed in proper quantity according to its kind and the nature of the soil. For these purposes the ground must have been previously well prepared by ploughings and harrowings, except in the particular case of drilling beans with one furrow. This operation is generally performed in the course of ploughing either by a person pushing forward a bean-drill barrow, or by attaching a hopper and wheel, with the necessary apparatus, to the plough itself. The mode of regulating the depth of the drill, and the quantity of seed delivered, must depend on the kind of drill used, and only requires attention in the holder. In drilling turnips the land is most generally made up into ridgelets twenty, seven or thirty inches centre from centre, by a single *bout* (go about) or return, of the common plough. The Northumberland machine, which sows two rows at once, is then drawn over them by one horse walking between the ridges without a driver, the holder at once performing that operation and keeping the machine steady on the tops of the drills. One of the two rollers of this machine smooths the tops of the ridges before the seed is deposited, and the other follows and compresses the soil and covers the seed.

3267 *In drilling corn* several rows are sown at once, and great care is requisite to keep the machine steady and in a straight line for most soils two horses and a driver are required for this purpose the driver aiding in filling the hopper with seed, &c.

3268 *In all cases of drilling* it must be recollected that the principal intention of the operation is to admit of horse-hoeing the crop afterwards hence the necessity of straight rows and uniform distances and hence also the advantage of burying the manure under the drill or row that it may not be exposed to the air in after-working.

3269. *Rolling* is the operation of drawing a roller over the surface of the ground with the view of breaking down the clods, rendering it more compact, and bringing it even and level or it may be limited to smoothing and consolidating the surface. It is practised both upon the tillage and grass lands, and is of much utility in both sorts of husbandry. In the former case it is made use of for the purpose of breaking down and reducing the cloddy and lumpy parts of the soil in preparing it for the reception of crops, and in rendering light soils more firm even and solid after the seed is put in. It is likewise found beneficial to the young crops in the early spring in various instances. In order to perform this operation in the most complete and effectual manner a roller of considerable weight is necessary and in order as much as possible to prevent the ground from being injured by the feet of the animals that draw it, as may frequently be the case where they follow each other in the same track, it is the best practice to have them yoked double, as by that means there will be less treading on the same portion of surface. Where two horses are sufficient to execute the work, more should never be made use of but if a third should be found necessary it may be attached as a leader in the middle before the other two a greater number of horses can seldom or never be of any material advantage in this sort of work. It is necessary to see that every part of the surface receives the due impression of the implement, and that the head lands are not injured by the turnings. On lands where the work is regularly performed, it will seldom be requisite to pass more than once in a place, but in other cases it may often be done more frequently with benefit, and in particular cases a more frequent repetition of the operation is absolutely requisite in order to bring the ground into a proper state.

3270 *In rolling grass lands* it is necessary to attend in a particular manner to the season, as it cannot be performed with advantage either when the surface is in too dry or too moist a condition. In these cases the work of rolling may be advantageously performed at different seasons, as in the beginning of the autumn, and in the commencement of the year or very early spring months but the latter is the most common period. In the drier descriptions of land it may frequently be performed, in the most beneficial manner after the land has been rendered a little soft by a moderate fall of rain but in those of the contrary sort it may be necessary to wait till the superabundant moisture be so much dried up, as to admit the animals employed in drawing the machine without subjecting the surface of the ground to poaching or other injury while the process is going on. The rolling of watered meadows, it has been remarked by Boswell, should be executed towards the latter end of February or beginning of the following month after the land has been left in a dry state for a week or ten days. The work should be performed along the panes, going up one side of the trenches and down the other and in the case of rolling the common hay lands, it is a good mode to proceed up one side of

the field and down the other, somewhat in a similar manner, as by that means the work may be the most completely executed.

3371 *Horse-raking*, or the collecting of the scattered straws of corn or hay crops by the rake, is an operation of little art or trouble in the execution. The proper implement being employed, it is generally drawn by one horse, conducted by a man, who walks behind, and, when the rake fills, lifts it up without stopping the horse, and always at the same place, so as to deposit the rakings in regular rows across the field. The same mode is followed whether in raking hay, corn, stubble, or weeds from fallow grounds.

3372. *Driving carts and waggons*, though the easiest of all operations, is very frequently shamefully performed by servants. Almost every body knows this, and it is humiliating to consider that we are considered the most inhuman nation in Europe in our treatment of horses. In most other countries these animals, and even oxen, are taught to obey the word of the driver but in Britain he requires both halter or rein, and a whip, and in most parts of England the slightest movement from right to left is indicated to the animal by the latter implement. Driving is more especially neglected, or wretchedly performed, near large towns, and especially round London, where little or no attention is paid to avoiding the ruts choosing the best part of the road going in a direct line altering the position of the load (by means of the back chain or the construction of the cart where that admits of it) in going up or down hill or seeing whether both horses (where two are used) draw equally. The reverse of this conduct ought to be that of a careful and humane driver who, being first certain that his cattle are properly yoked, and his load fairly adjusted so as to be neither too heavy nor too light for the wheel or shaft horse, will see that they proceed along the best part of the road in a straight line, avoiding the ruts when deep or unequal that all the horses draw equally as far as practicable, that proper care and timely precautions be taken to avoid other machines meeting or passing and that no sudden motion or jerk of the horses be required on any occasion. In dividing the road where it is steep or in a bad state, the horses ought to be drawn aside gradually, and gradually led on again it being easier to descend or ascend either a good or bad convex road obliquely than at an acute angle. Lastly servants ought on no account to be allowed to ride on laden carts or waggons, especially the former or to walk at a distance from them either before or behind. There are many other points which require attending to in this department of agriculture such as not striking animals on the head or legs, nor kicking them, nor using a pole or handle of any implement that may be at hand, in administering chastisement but these must be left to the care and discretion of masters, whose interest it is to be most vigilant in watching those who are engaged in this department.

3373. *One mode of lessening the evils of careless driving* and inhumanity to animals consists in employing chiefly married servants, and, as is generally the case, letting such have the exclusive care and working of one pair of horses. Such men are roused, and remain much longer in their situations, than single men, and are therefore more likely to feel an interest in the welfare and good condition of their horses, as well as in the good opinion of their employer.

3374 *Driving cattle in a threshing-machine* required particular care before the ingenious invention, described § 2755 to equalise the draught of the different animals where this invention is applied it requires little more than calling to such of the cattle as have a tendency to relax in their exertions.

### SECT. III. *Labours and Operations with the Crop, performed with the Aid of Cattle.*

3375. *Labours with the crop* chiefly comprise stacking and houghing.

3376. *Stacking* is the operation of building or piling up unthreshed corn, hay, straw, or other dried crops, in convenient forms, and so as to admit of their being thatched as a defence from the weather. Stacks are of various forms and dimensions, according to circumstances in some districts they are formed square or oblong, both for hay and corn but where threshing-machines are in use, the circular base with cylindrical body, diverging a little at the eaves, and a conical top, is decidedly preferred, as being more convenient in size and form, and better adapted for early stacking in wet seasons than any other. For hay the form of the stack is a matter of less consequence the long square or oblong shapes are perhaps the most safe and convenient, especially when not too broad, as they are the most suitable to cut from in trussing hay for sale.

3377 In respect to the *uses of corn-stacks of the square sort* they of course vary greatly according to circumstances, but they should never be made too large, as there is a great deal more risk in securing and getting in the grain from them and from their being built at different times, they do not settle altogether in so perfect a manner, or resist the effects of the weather and keep the grain so well, as those of less dimensions that can be completed at once and, in addition, they are less convenient in the threshing out, especially where the flail is employed. The chief advantages they possess, are those of taking something less in thatch and labour in covering them.

3278. *The proper use of the hay-stack* should probably be different in some degree according to the state and nature of the hay but a muddling use is perhaps the best, say from twenty to thirty loads of about one ton each, as there are inconveniences in both small and large stacks, the former having too much outside, while the latter are liable to take on too much heat, and at the same time permit less moisture to be preserved in the hay. In small stacks the bellying forms with very narrow bottoms have often much advantage and are in some districts termed *sheep-stacks*, probably from the slovenly practice of sheep having been permitted to feed at them.

3279. *In building every description of stack* the stem or body should be so formed as to swell gradually outwards, quite up to the part termed *the eaves* as by this method it is more perfectly secured against the entrance of moisture, and at the same time requires a less space of stand to rest upon and, when the building of them is well performed, they have equal solidity and stand in as firm a manner.

3280. *The stem* should contain about two thirds, and the roof one third, of the whole stack. If it be built on a frame, the stem should contain less and the roof more. If on a bottom, the reverse. The corners of the stem should not be built too sharp, but should be carried up rather roundish; by which the sides will look fuller and the swell given by the pressure will be more perceptible.

3281. *The ends of the roof* should have a gentle projection answerable to the stem; and the sides should be carried up rather convex, than flat or concave. Perhaps a roof gently convex shoots off the rams better than any other.

3282. *Where corn is stacked that has not been sheaved*, and in building hay-stacks, it is the usual practice to have a number of persons upon the stack, the corn or hay being forked up and deposited on the different sides all round in a similar method. After this, other parcels are laid all round on the inside of these so as to bind them in a secure manner from slipping outwards the operator proceeding in the same manner till the whole of the middle space is perfectly filled up when he begins another course in the same method, and goes on in this mode, with course after course, till he has raised the whole of the stem when he begins to take in for the roof in a very gradual manner in every succeeding course, until the whole is brought to a ridge or point according to the manner in which the stack is formed. But for the purpose that the roofs may throw off the water in a more perfect and effectual manner they should be made so as to have a slight degree of fulness or swell about the middle of them and not be made flat, as is too frequently the practice with indifferent builders of stacks.

3283. *In stacking where the corn is bound into sheaves* there is seldom more than one person employed in managing the work of building the stack, except in cases where the dimensions are very considerable in which cases it is found necessary to have a boy to receive the sheaves from the pitcher and hand them to the man who builds the stack. In executing the work, it is of the utmost importance that the centre of the stack be constantly kept in a somewhat raised state above the sides, as the sheaves have thus a sloping direction outwards, by which the entrance of moisture is more effectually guarded against and prevented. To accomplish this in the most perfect manner the workman begins in the middle of the stand or staddle, setting the sheaves together so that they may incline a little against each other placing the rest in successive rows against them till he comes to the outside, when he carries a course of sheaves quite round, in a more sloping manner than in the preceding courses. The bottom of the stack, being formed in this way it is afterwards usual to begin at the outside, and advance with different courses round the whole, placing each course a little within the other so as to bind them in an exact and careful manner till the stacker comes to the middle. All the different courses are to be laid on in a similar manner until the whole of the stem is raised and completed, when the last outside row of sheaves is, in most cases, placed a very little more out than the others, in order to form a sort of projection for the eaves, that the water may be thrown off more effectually. But in cases where the stems of the stacks are formed so as to project outwards in the manner already noticed, this may be omitted without any bad consequences, as the water will be thrown off easily without touching the waste of the stack. The roof is to be formed by placing the sheaves gradually a little more in and in, in every course until it comes to a ridge or point according to the form of the stack, as has been already observed. But in forming and constructing this part of the stack, great care should constantly be taken to give the eave-ends of the sheaves a sufficiently sloping direction upwards, in order that they may be the better secured from wetness and to the outside should be given a rounded form, in the manner that has been already noticed.

3284. *A funnel or chimney* is frequently formed or left in circular stacks, especially in wet districts, in order to prevent their taking on too much heat where these funnels are not formed with the basement of timber iron, or masonry as already shown (2908.) they are produced by tying a sheaf up in a very tight manner and placing it in the middle on the foundation of the stack, pulling it up occasionally as the building of the stack proceeds all round it. In setting up ricks in bad harvests, it is a practice in some places, particularly with barley crops, to have three or four pretty large poles tied together, by winding straw ropes round them, set up in the middle, round which the stacks are then

built. But except the stacks are large, or the grain when put into them in an imperfect condition, such openings are quite unnecessary.

3285. *The stacking of hay* requires much care and attention in the person employed for the purpose, though less than that of building corn stacks. There should constantly be a proper stand or foundation, somewhat raised by wood or other materials, prepared for placing the stacks upon but nothing of the coping kind is here necessary. In the business of stacking hay the work should be constantly performed as much as possible, while the sun is upon the hay, as considerable advantage is thus gained in its quality and it is necessary to have a stacker that has been accustomed to the business, and a proper number of persons to help upon the stack, in order that it may be well spread out and trodden down.

3286. *The building of hay-stacks* should be conducted much in the same way as the building of stacks of loose grain (3282.) the middle of the stack being always well kept up a little higher than the sides, and the sides and ends well bound in by the proper application of the successive portions of hay as the work advances and during which it is a good way, where there are plenty of hands, to have the sides and ends properly pulled into form, as by this means much after labour is prevented. It is likewise of advantage, that the hay should be well shaken and broken from the lumps, during the operation of stacking. The form in which the stacks are built is not of much consequence but, if large, and made in the square form, it is better not to have them too broad, or of too great width, as by this means they are less apt to heat. With the intention of preventing too much heat, sometimes in building hay stacks, as well as those of the grain kind, holes, pipes, and chimneys, are left in the middle, that the excessive heat may be discharged but there is often injury sustained by them, from their attracting too much moisture.

3287. *The hay-stacks of Middlesex* it is observed by Muddleton, are more neatly formed and better secured than any where else. At every vacant time, while the stack is carrying up the men are employed in pulling it with their hands into a proper shape and about a week after it is finished the whole roof is properly thatched, and then secured from receiving any damage from the wind, by means of a straw rope extending along the eaves, up the ends, and near the ridge. The ends of the thatch are afterwards cut evenly below the eaves of the stack, just of sufficient length for the run water to drip quite clear off the hay. When the stack happens to be placed in a situation which may be suspected of being too damp in the winter a trench of about six or eight inches deep is dug round, and nearly close to it, which serves to convey all the water from the spot, and renders it perfectly dry and secure.

3288. *The stack guard* (fig. 519) or covering of canvas, is employed in some districts to protect the stack while building in a wet season. In Kent and Surrey, the half

worn sails of ships are made use of for this purpose, though in most parts of the north a covering of loose straw or hay is found sufficient in ordinary cases but where, from a continued rain, the stack is penetrated some way down, a part is removed on recommencing, and dried before being replaced. It is observed by Marshall, that a sail-cloth thrown over and immediately upon the hay of a stack in full heat, is liable to do more injury by increasing the heat, and at the same time checking the ascent of the steam, than service in shooting off rain water. The improved method of spreading the cloth he describes as follows: two tall poles (a, a) are inserted firmly in two cart wheels (b, b), which are laid flat upon the ground at each end of the stack, and loaded with stones to increase their stability. Another pole of the same kind, and somewhat longer than the stack, is furnished at each end with an iron ring or hoop, large enough to admit the upright poles and to pass freely upon them. Near the head of each of the standards is a

pulley (*c, c*) over which a rope is passed from the ring or end of the horizontal pole, by which it is easily raised or lowered to suit the given height of the stack. A cloth being now thrown over the horizontal pole, and its lower margins loaded with weights, a complete roof is formed and neatly fitted to the stack, whether it be high or low wide or narrow the eaves being always adjusted to the wall plate, or upper part of the stem of the stack thus effectually shooting off rain water, while the internal moisture or steam escapes freely at either end as the wind may happen to blow. This contrivance is readily put up or taken away the poles being light, are easily moved from stack to stack, or laid up for another season, and the wheels are readily removed or returned to their axles. On the whole, it answers as a good substitute for the improved construction brought into use by Sir Joseph Banks, and is much less expensive. This construction, instead of the ring running on the poles, has blocks and tackle (*c, c*) and instead of weights to distend the cloth, ropes (*d, d*) are used to tighten it and keep it detached from the sides of the stack, so as to admit a more free circulation of air.

3289 A stacking stage (fig 520) or scaffold, has been contrived for finishing the

upper parts of high stacks, but it can seldom be requisite when a judicious use of stack is adopted. This stage, which consists of a frame (*a*) and a movable platform (*b*), easily understood and constructed, is set against the stack, when it becomes so high that it is inconvenient to pitch on to it from the cross plank of a waggon. The platform is commonly fixed by means of the chain pins and holes, about fourteen feet from the ground, which is about the height of a waggon load of hay. Were it fixed lower it would be of no use and were it fixed much higher it would be found

too high for a man to pitch on to when the waggon should have become nearly empty.

3290. The term *housing* is chiefly applied to crops of the root kind, as potatoes, carrots, turnips, &c. Potatoes being gathered in dry weather are preserved by being laid up in heaps, secured from rain and frost more particularly and from the weather generally whether dry, moist, cold, or hot. The mode of doing this in some places is to form them into heaps on the surface of the soil, covering them with a thick layer of straw and on that another of earth. Sometimes also, where the soil is dry they are buried in pits and similarly covered but, for common agricultural purposes, by much the best mode is to lay them up in a house, securing them from all extremes of weather by a covering of straw. By this mode they are much more easily got at when a portion is wanted, than by any other in use.

3291 In housing carrots, and Swedish or yellow turnips, the same modes may be adopted as for potatoes but in housing white turnips, as they are apt to rot when heaped up, the best mode is to spread them thinly on any surface covered from the rain, but freely exposed to the circulation of air. This mode, it must be evident, can only be adopted to a limited extent, and, indeed, is only resorted to as a precautionary measure during winter, when frosts, snows, or continued rains, might interrupt the lifting and carting from the fields of the usual supplies for feeding stock.

3292 Various modes of housing and preserving these and other roots, will be treated of as each particular crop comes into notice in a succeeding Book (VI)

### CHAP. III

#### *Scientific Operations, and Operations of Order and general Management*

3293 All the operations which have hitherto been described require to be practically known to every farm servant or operative agriculturist the few about to be described belong more particularly to the superintendent or master they may be arranged as scientific operations, and operations of order and management.

#### *SECT. I Scientific Operations required of the Agriculturist.*

3294 The scientific operations required of the agriculturist are chiefly the measuring surfaces, measuring solids, taking the levels of surfaces, dividing lands and valuing lands, timber, leases, and farming stock. A knowledge of the more common practices of surveying, measuring, and the calculation of annuities, may be considered as essential to every agriculturist, whether farmer land agent, or proprietor who is desirous of having clear ideas on the subject of letting labour hiring or letting farms, or purchasing estates. Such knowledge is not to be expected in detail in this work, but must be procured from the ordinary school and annuity books and is indeed implied in a regular education.

All we propose here is to direct the reader's attention to the most important points of the art of surveying, and lay down the leading principles of valuing agricultural property

**SUBJECT 1** *Measuring relatively to Agriculture.*

3295. *The measuring of land*, or other objects, comprises three distinct operations, viz. taking the dimensions of any tract or piece of ground, delineating or laying down the same in a map or draught, and calculating the area or superficial contents. The dimensions on a small scale are best taken by rods of wood, but in all ordinary and extensive cases by a chain of iron, being less likely to contract or expand by changes of temperature than cord lines or tapes. In measuring a simple figure, such as a square field, nothing more is necessary than to take the length and breadth, which multiplied together give the superficial area; but as few fields are square, or even right angled, it becomes necessary to adopt some guiding line or form within the field, and from that line or form to measure to the different angles, so as to be able, from the dimensions taken, either to calculate the contents at once, or to lay down the form of the field on paper according to a certain scale, or proportion to its real size, and from that to take dimensions and calculate the contents. The simplest and most accurate mode of ascertaining the contents of all irregular figures is by throwing them into triangles; and this also is the most accurate mode of measuring and protracting a whole landed estate, however large. In short, a triangle is the form universally adopted, whether in surveying a single field, or a whole kingdom. To find the contents of a triangle, every body knows that it is only necessary to multiply half the perpendicular into the base. These two principles, properly understood, form the foundation of measuring, protracting, and estimating the contents of territorial and all other surfaces. In surveying hilly lands, an allowance is made both in protracting them, and calculating their contents, well known to surveyors, and not necessary to be entered into here.

3296. *In measuring solid bodies*, the rule is to "find the area of one end, and multiply that by the length." This rule is of universal application, whether to land, as in excavating or removing protuberances to ricks of corn, heaps of dung, timber or water. The area of one end, or of one surface, whether the end, side, top, or bottom, is found exactly on the same principles as in ascertaining the superficial contents of land; and if the figure diminishes in the course of its length, as the top of a rick, or the trunk of a tree, the mean length or half is taken as a multiplier.

3297. *Measuring objects by the eye*, though a mode that can never be depended on as the foundation for any important calculation or transaction, yet should be constantly practised by young men, for the sake of gaining habits of attention, and acquiring ideas as to number and quantity at first sight. The principle on which this sort of eye measurement is acquired, is that of ascertaining the actual dimension of some near object, and applying it as a measure to all the others seen beyond it. Thus, if a man is seen standing by a post or a tree at a distance, taking the height of the man at five and a half or six feet; apply the figure of the man to the tree, and find how many applications will reach its top; that number multiplied by the ordinary height of a man, will of course be a near approximation to its height. Again supposing this tree one in a row or avenue, then to estimate the length of the avenue, measure the third or fourth tree by the man, and measure by the same means the distance of that tree from the first, then state the question thus: As the difference between the height of the first and fourth tree is to the horizontal distance between them, so is the difference between the first and last tree of the avenue, to the length of the avenue. In this way, the length and breadth of a field may be estimated by observing the height of the hedge at the nearest side, and the apparent height at the farthest points. The breadth of ridges and their number teams at work or cattle grazing, or accidental passengers, are all objects of known dimensions, which may be made use of in this way of estimating the contents of lands. In regard to houses, the doors, and windows, and use of bricks, stones, boards, tiles, &c. are obvious and certain guides.

3298. *The recollection of surfaces and of country* is a matter of considerable interest to every one, but especially to the agriculturist. The most effectual mode of impressing scenery on the memory is by the study and practice of sketching landscape. In addition to this, it will be useful to pay attention to the natural surface and productions, as kind of tree or crop, hills, valleys, flats, lakes, rills, &c. also to the distant scenery, as whether flat, hilly, cultivated, waste, woody, or watery; what processes are going on; what the style of houses, dress, &c. Having attended to these details, the next and the most important aid to the memory is to recollect what portion of country already known to us it most resembles.

3299. *In endeavouring to recollect the surface and objects composing an entire estate* some leading central object, as the house, should be fixed on, and the bearings of other objects relative to it ascertained in idea. Then, either by going over the estate, or by a favourable position on the house-top or some other eminence, the outline of the fields, or other

scenery nearest the house, may be taken down or remembered, and also the distant scenery, or that exterior to the estate. In riding through a country which it is desired to recollect, a sketch should be made in imagination of the road and the leading objects adjoining, another of what may be called the objects in the middle distance and, finally, one of the farthest distance. If instead of the imagination, a memorandum book were used, and the sketches accompanied with notes, the country examined would be firmly impressed on the memory. In this way temporary military maps are formed by the engineers of the army in a few hours, and with astonishing accuracy.

#### SUMMARY 2. Taking the Levels of Surfaces.

3500. *Leveling*, or the operation of taking the levels of surfaces, is of essential use in agriculture, for ascertaining the practicability of bringing water to particular points in order to drive machinery, for irrigation for roads led along the sides of hills for drainages, and various other purposes. There are few works on the earth's surface more useful, grand, and agreeable, than a road ascending, passing over, and descending a range of steep irregular mountains, but every where of the same and of a convenient slope next to this is a canal passing through an irregular country, yet every where on the same level.

3501. Two or more places are said to be on a *true level*, when they are equally distant from the centre of the earth. Also, one place is higher than another or out of level with it, when it is farther from the centre of the earth and a line equally distant from that centre in all its points, is called the line of true level. Hence, because the earth is round, that line must be a curve, and make a part of the earth's circumference, or at least be parallel to it, or concentric with it.

3502. The line of sight given by the operation of leveling is a tangent, or a right line perpendicular to the semidiameter of the earth at the point of contact, rising always higher above the true line of level, the farther the distance is, which is called the *apparent line of level*, the difference of which is always equal to the excess of the secant of the arch of distance above the radius of the earth.

3503. The common methods of leveling are sufficient for conveying water to small distances, &c. but in more extensive operations, as in leveling for canals, which are to convey water to the distance of many miles, and such like, the difference between the true and the apparent level must be taken into the account, which is equal to the square of the distance between the places, divided by the diameter of the earth, and consequently it is always proportional to the square of the distance or from calculation almost eight inches, for the height of the apparent above the true level at a distance of one mile. Thus, by proportioning the excesses in altitude according to the squares of the distances, tables showing the height of the apparent above the true level for every hundred yards of distance on the one hand, and for every mile on the other, have been constructed. (See Dr Hutton's *Mathematical Dictionary* art. *Level*.)

3504. The operation of leveling is performed by placing poles or staves at different parts or points from which the levels are to be taken, with persons to raise or lower them, according to circumstances, when the leveling instrument is properly applied and adjusted. In describing the more common levels used in agriculture (2497) we have also given some account of the mode of using them for common purposes. Their use, as well as that of the different kinds of spirit levels, will be better acquired by a few hours practice with a surveyor than by any number of words and indeed in practice, whenever any very important point or series of levels is to be taken, it will commonly be found better to call in the aid of a land surveyor than to be at the expense of implements to be seldom used, and with which errors might easily be made by a very skilful person not accustomed to their frequent use.

3505. Leveling to produce an even line (fig 591) as in road-making, whether that

line be straight or curved in direction can only be determined on an irregular surface by measuring down from an elevated level line (a) or from level lines in parallel directions,  
M in 4

and so transferring the points by horizontal levels to the proper line. Straight rods are the ready means of measuring down, and the points must be marked by hillocks or hollows (b), or by smooth-headed stakes driven into the surface, and protruding above, or sunk under it, according to the obstructions.

3306. *Lands of uniform declivity or acclivity* (fig 531 a, c, e) are readily formed on the same principle. In this and the former case, the common level and the boring piece (a and d), with measuring-rods and stakes, are all the instruments required.

### SUMMARY 3. Division and laying out of Lands.

3307 *The division of lands is one of the most important and not the least difficult parts of the land surveyor's art.* In intricate cases, as in the subdivision of large estates or commons, the professional surveyor will generally be resorted to but it is essential for the land-steward and proprietor, and even for the farmer or professional cultivator to know the general principles on which this business is founded. We shall therefore shortly develop these principles from Dr Hutton's valuable Dictionary and next offer some general rules, of our own for ordinary cases of dividing and laying out lines.

3308 *In the division of commons* after the whole is surveyed and cast up and the proper quantities to be allowed for roads, &c. deducted, divide the net quantity remaining among the several proprietors, by the rule of fellowship, in proportion to the real value of their estates, and you will thereby obtain their proportional quantities of the land. But as this division supposes the land, which is to be divided, to be all of an equal goodness, you must observe that if the part in which any one's share is to be marked off be better or worse than the general mean quality of the land, then you must diminish or augment the quantity of his share in the same proportion.

3309 *Or divide the ground among the claimants in the direct ratio of the value of their claims,* and the inverse ratio of the quality of the ground allotted to each that is, in proportion to the quotients arising from the division of the value of each person's estate, by the number which expresses the quality of the ground in his share.

3310. *But these regular methods cannot always be put in practice;* so that, in the division of commons, the usual way is to measure separately all the land that is of different values, and add into two sums the contents and the values then the value of every claimant's share is found by dividing the whole value among them in proportion to their estates and lastly a quantity is laid out for each person, that shall be of the value of his share before found.

3311 *It is required to divide any given quantity of ground, or its value into any given number of parts, and in proportion to any given number — Rule* Divide the given piece, or its value, as in the rule of fellowship by dividing the whole content or value by the sum of the numbers expressing the proportions of the several shares, and multiplying the quotient severally by the said proportional numbers for the respective shares required, when the land is all of the same quality. But if the shares be of different qualities, then divide the numbers expressing the proportions or values of the shares, by the numbers which express the qualities of the land in each share and use the quotients instead of the former proportional numbers.

	Ac.	R.	P.
A =	4	2	30
B =	9	1	30
C =	14	0	10
D =	23	1	30
E =	37	2	00
F =	46	3	30
G =	70	1	10
H =	85	5	00
Sum =	300	0	00

Ex. 1. If the total value of a common be 2500*l.* It is required to determine the values of the shares of the three claimants A B, C whose estates are of these values, 10,000*l.* 15,000*l.* and 25,000*l.* The estates being in proportion as the numbers 2, 3, 5, whose sum is 10, we shall have  $2500 \div 10 = 250$ ; which being severally multiplied by 2, 3, 5 the products 500, 750, 1250, are the values of the shares required.

Ex. 2. It is required to divide 300 acres of land among A B C, D E, F G and H, whose claims upon it are respectively in proportion as the numbers 1 2, 3, 4, 5, 6, 10, 15, 20. The sum of these proportional numbers is 64, by which dividing 300, the quotient is 4 ac. 2*r.* 30 p. which being multiplied by each of the numbers, 1 2, 3, 4, &c. we obtain for the several shares as annexed

Ex. 3. It is required to divide

522

780 acres among A B, and C, whose estates are 1,000*l.* 3,000*l.* and 4,000*l.* a year the ground in their shares being worth 5, 8 and 10 shillings the acre respectively. Here their claims are as 1 3, 4 and the qualities of their land are as 5, 8, 10; therefore their quantities must be as one fifth three eighths, two fifths or by reduction as 8, 15, 16. Now the sum of these numbers is 39, by which dividing the 780 acres, the quotient is 20 which being multiplied severally by the three numbers, 8, 15, 16, the three products are 160, 300, 320, for the shares of A B, C, respectively

3312 *To cut off from a plan a given number of acres, &c. by a line drawn from any point in the side of it — Rule* Let a (fig 522.) be the given point in the plan, from which a line is to be drawn cutting off suppose 5 ac. 2*r.* 14 p. Draw a b cutting off the part a b c as near as can be judged equal to the quantity proposed, and let the true quantity of a b c, when calculated, be only 4 ac.

3 r 20 p. which is less than 5 ac. 2 r 14 p. the true quantity by 0 ac. 2 r 34 p. or 71,250 square links. Then measure  $a b$ , which suppose = 1,234 links, and divide 71,250 by 617 the half of it and the quotient, 115 links, will be the altitude of the triangle to be added, and whose base is  $a, b$ . Therefore, if upon the centre  $b$ , with the radius 115 an arc be described, and a line be drawn parallel to  $a, b$ , touching the arc, and cutting  $b, d$  in  $d$  and if  $a, d$  be drawn, it will be the line cutting off the required quantity  $a, d, c, e$ . On the other hand, if the first piece had been too much, then  $d$  must have been set below  $b$ . In this manner, the several shares of commons to be divided, may be laid down upon the plan, and transferred thence to the ground itself.

3313. *The simplest mode of dividing lands*, and that by which the agriculturist will make fewest errors, is by *trial and correction*. Thus, supposing a piece of unenclosed land of irregular shape to contain thirty-eight acres and a half and it is desired to lay it out in three fields, each of the same extent. Take a plan of the field, and lay it down on paper divide it into three parts as near as possible by the eye then ascertain the contents of one of the outside divisions, which will be either somewhat too little or too much. Suppose it too little by half a rood then, as the length of the straight line of the division is 1000 links, and 1000 links in length and 100 in breadth make an acre, and as half a rood is the eighth of an acre, it follows that by extending the line the eighth part of 100 links, or 12 4 links at both ends, or 24 8 links at one end, the requisite quantity will be added. Then go through the same operation with the projected field on the other extreme of the plot and this being corrected, the middle field must necessarily be of the exact contents of each of the two others but to prove the whole, this field also may be tried in the same manner.

3314 *In dividing a field with a view to sowing different crops in certain proportions* say, for example, one acre and a half of common turneps, one acre of Swedish turneps, three quarters of an acre of potatoes, and five acres of peas. Suppose the field a parallelogram or nearly so then first ascertain the length of the ridges, and next state the question thus — Such a length being given, required the breadth to give a fourth of an acre — that being the smallest fraction in the proportions to be laid out then, if the length of the ridges be ten chains, the breadth requisite to give a quarter of an acre will be 25 links consequently a breadth of five times that space will be required for the common turneps four times for the Swedish turneps three times for the potatoes and twenty times for the peas.

3315 *In all more intricate cases*, first lay down the plan of the space to be divided on paper to a large scale, say a chain to an inch then cover the paper with lines, drawn so as to form squares, each square containing a certain number of feet and yards, or say a pole each then on these squares adjust the figure, whatever it may be thus, supposing it desired to lay out a thicket of trees on the face of a hill, the outline of which shall resemble the outline of the profile of a horse, dog or say a human head, and yet shall contain only one acre lay down the outline of the horse or head on a large scale and divide it into squares then by trial and correction ascertain what each square must necessarily contain. Say that there are 150 entire squares and 40 parts of squares, making up in all 160 squares each of these squares must of course contain exactly one pole, or 625 links, and their sides the square root of that number, or 25 links. From these data it is easy to lay down the figure with perfect accuracy.

3316 *The laying out lines on lands*, for the purposes of roads, fences, &c requires to be well understood by the agriculturist. On a plain surface, the business of tracing straight lines is effected by a series of poles, so placed that the one nearest the eye conceals all the rest. Where a straight line is to be indicated among objects or inequalities not more than fifteen or twenty feet high, its plan or track on the earth ( $a, b$ , fig 593 )

#### SUMMARY. 4. *Estimating Weight, Power, and Quantities*

3319 *Ascertaining the weight of objects is a part of agricultural knowledge, no less necessary than that of measuring their superficial or solid contents. In all ordinary cases, as of grain, roots, bundles of straw, bushels of lime, &c., this is best done by a common steelyard, suspended from a beam or a triangle of three posts. Cart or waggon loads are weighed on those well-known platforms sunk in the ground at toll gates or sometimes by steelyards on a very large scale. Cattle are weighed by machines of a particular kind, which have been already described (2566. to 2568.) The weighing of cattle and grain chiefly concerns the farmer and is of consequence, in the first case, to ascertain the progress of fattening animals, or the weight of those ready for the butcher and, in the second, to determine the quantity of flour that may be produced from a given quantity of grain.*

3320. *Estimating the quantity of power requisite to draw any implement or machine is performed by the intervention of the draught machine already described (2563.), between the power and the implement. It would not be difficult to construct all agricultural implements with a fixed draught-machine and index, which would at all times, when they were at work, shew the amount of power employed in moving them but such an arrangement would be of little use.*

3321 *Estimating the quantity of work which servants and cattle ought to perform in a given time, is an art that ought to be familiar to every agriculturist. In general no absolute rule can be laid down, because so much depends on soils, roads, cattle, and other circumstances but in every particular case, the rate or market price of labour per day being given, and the quantity of work ascertained which a man can fairly perform in a certain time, a rate per yard, pole or acre, or per solid quantity if materials are to be moved, can easily be determined on. A farmer should know by memory the number of ridges or of single furrows, or bouts, which it requires to make an acre on every field of his farm. This will aid him in every operation that requires to be performed on these fields, the quantity of manure, seed, ploughings, harrowings, hoeings, mowing, reaping, raking, &c. as well as in estimating the produce, whether corn, hay, roots, or the number of cattle or sheep that may be grazed there for any given time.*

3322 *Road work, ditching, hedging, draining, trenching, &c. ought to be subjected to similar calculations, so as if possible to let out all work not performed with the master's own men and cattle, by contract or quantity instead of by time. As spade work is nearly the same in most parts of the country, certain general rules have been laid down by canal contractors and others, which, though seldom strictly followed up, it may be useful to know. Thus in moving ground, as in digging a drain or the foundations of a building, if the soil is soft, and no other tool than the spade is necessary, a man will throw up a cubic yard of 27 solid feet in an hour, or 10 cubic yards in a day. But if picking or hacking be necessary an additional man will be required and very strong gravel will require two. The rates of a cubic yard, depending thus upon each circumstance, will be in the ratio of the arithmetical numbers 1, 2, 3. If therefore, the wages of a labourer be 2s. 6d. per day, the price of a yard will be 3d. for*

cutting only, 6d. for cutting and hecking, and 9d. when two hockers are necessary. In sandy ground, when wheeling is requisite, three men will be required to remove 30 cubic yards in a day to the distance of 30 yards, two filling and one wheeling but to remove the same quantity in a day, to a greater distance, an additional man will be required for every 30 yards.

3323. *To find the price of removing any number of cubic yards to any given distance.* Divide the distance in yards by 30, which gives the number of wheelers add the two cutters to the quotient, and you will have the whole number employed multiply the sum by the daily wages of a labourer and the produce will be the price of 30 cubic yards. Then, as 30 cubic yards is to the whole number so is the price of 30 cubic yards to the cost of the whole. *Example* — What will it cost to remove 2,750 cubic yards to the distance of 120 yards, a man's wages being three shillings per day? First,  $120 \div 30 = 4$ , the number of wheelers, then  $+ 2$  fillers = 6 men employed, which, at three shillings per day gives twenty-four shillings as the price of 30 cubic yards, then  $30 \times 24 = 720$  and  $24 \times 2,750 \div 30 = 2,200$ .

#### SUMMARY 5 *Estimating the Value of Agricultural Labour and Materials, Hints and Tillage.*

3324 *Estimating the value of work done* is a necessary part of agricultural knowledge and is founded upon the price of labour and the time of performance. The price of labour is every where determined by the operations of the public, and therefore in any given case can seldom admit of much difference of opinion. In a theoretical view of the subject the proper wages for a labourer in England has been considered, for ages, to be a peck of wheat and that of a horse the amount of his keep, expenses of a year's shoeing and ten per cent. on his value or cost price at a far age added together and divided by the number of days each horse is supposed to work in a year this brings the value of the day's work of a horse to something more than once and a half the value of the day's work of a man so that supposing a labourer's wages two shillings per day a man and a pair of horses would be worth eight shillings per day. This, however it must be acknowledged, is a calculation not always to be depended on, as local circumstances continually intervene to alter the proportions. In all cases of valuing labour therefore, all that the valuator can do is to ascertain the local price, and to estimate from his own experience the time requisite to perform the work.

3325 *In estimating the value of labour and materials* considerable difficulty occurs in some departments of agriculture. Thus, in valuing fallows and sown crops it is often a nice point to determine satisfactorily the value of the manure or other dressings and in valuing the tillages, or the condition of the arable lands of an out-going tenant, regard must be had not only to the actual number of ploughings a field may have been subjected to the preceding or current year but to the position which the state of that field holds in the rotation, and to the value which may still be in the soil from manures or linings given to former crops. Supposing a field fallowed, limed, and dunged in the year 1890, and that when it fell to be valued in the spring of the year 1894, it was drilled with beans on one furrow, it would be no adequate compensation for the tenant to be paid for one ploughing, the beans, and the drilling the fallow, the dung, and especially the lime given in 1890, must be considered as extending their influence even to this crop and therefore an allowance ought to be, and generally is, made for these three articles, besides the mere value of the labour and seed. What this allowance should be it does not seem easy to determine land valuers and appraisers have certain rules which they go upon which are known to few but themselves, but which, having ourselves been initiated in the business, we know to differ considerably in different parts of the country. Some calculate that the value of dung extends to the fourth year and declines in a geometrical ratio, or in the proportion 1, 2, 4, 8 others limit its effects to three years. Lime is allowed in some places to produce effects for three years only and in others, especially on new lands, for twelve and fourteen years and its value is generally supposed to decline in the proportion of 1, 2, 3 &c. Naked fallow is generally considered as of beneficial influence for five years, where it occurs every seven or eight years, and shorter periods in proportion. A crop sown on a single furrow after a drilled crop which has been manured, is considered as partaking of the manure or other dressings according to the extent to which these have been given, and generally in the same ratio as in manured fallows.

3326 *In estimating the value of materials alone* the first thing is to ascertain their quantity and the next their market price. Thus, in the case of heaps of manure, the cubic contents must first be found, by finding the area of the base of the heap, and its mean depth, and multiplying the one into the other next, the quality of the material must be examined, and the expense of purchasing it in the nearest town or source of purchase, with the addition of the expense of carriage to the spot where it lies. Ricks, whether of straw or hay are valued in a similar manner. Crops in a growing state are valued according to what they have cost, including tillage, manures, seed, rent, taxes, and other outgoings, and ten per cent. on the outlay of capital, crops arrived at maturity.

ity are valued according to their quantity and quality deducting the expenses of reaping, threshing, &c. In coal countries an allowance is made for thorn-hedges which have been newly cut; but the reverse is the case where fuel is scarce, an allowance being made according to the quantity of brush or lop on the hedge. The lop of pollards, and prunings of hedgerow trees to a certain height, are generally valued to the tenant but a better mode is for the landlord to take the timber trees entirely under his own management.

3327 *In valuing live stock*, a variety of circumstances require to be taken into consideration. The value of all young animals may be considered as prospective the chief value of others depends on their breeds of some, on accident or fashion and of fed animals on their actual value to the butcher Draught cattle may be valued on an abstract principle, derived from the probable value of their lives and labour but in general nothing is to be depended on but a knowledge of the market price, and this ought to be familiar to every valuator.

3328 *In valuing buildings* regard must be had to their absolute use as such and to their effect on the value of surrounding property In the case of buildings merely useful as farmhouses, it will sometimes happen that more buildings are erected than the most approved mode of husbandry requires, as in the case of large barns and granaries, ornamental pigeon-houses, &c. these can be valued on no other principle than that of the value of the materials, supposing them taken down and, in regard to an in-coming tenant, they are to be considered as a drawback, rather than as of any value.

3329. *In valuing orchards, hop-grounds, oser plantations, and similar crops*, it is usual for the first two or three years after planting to allow only the cost, rent, all outgoings, and ten per cent. on their amount but afterwards, the trees and plants having taken with the soil, and promising abundant crops, they are valued prospectively in the mode in which we shall next describe as applied to young plantations of timber-trees.

3330. *In valuing young plantations* when they are only of two or three years' growth, it is usual to proceed as in valuing orchards but afterwards, when their growth is becoming rapid, and the fences in a sufficient state, the plantation is valued prospectively in the following manner:—The contents being known, and the number of healthy young trees per acre ascertained, then their value at any distant period, not exceeding twenty or twenty five years, is estimated and whatever sum that estimate amounts to, the present value of that sum will give an idea of the value of the plantation allowing liberally for accidents to the trees, and other unforeseen circumstances. Thus, suppose a plantation of oaks, intended as copse or actually established as such, to have grown four years, its present value would be next to nothing but if arrived at its twentieth year it would fetch fifty pounds per acre. Then the question is, required the present value of fifty pounds due sixteen years hence, the market price of money being five per cent. ? and this, according to any of the modern annuity tables (say *Bayley's* 4to. 1808 tab iv.), is 22. 18s. This principle is applicable to all kind of valuing by anticipation and there is no other mode of valuing applicable to young plantations.

3331 *In valuing saleable trees*, their number per acre, or their total number, being ascertained, an average value must be made of each tree, according to its worth as fuel timber fence-wood bark for the tan-pit, and other particulars, due allowance being made at the same time for the expenses of felling, cutting up sorting, carriage, &c. The usual practice in this case, as well as in the valuation of copse-woods, will be given in treating of wood-lands in the succeeding PART of this work.

3332. *In valuing fields for rent*, regard must be had to their soil and subsoil, as of the greatest importance; next, to their aspect, form, length, and style of ridges and, lastly as to the sort of crops or rotation which may be followed on them, and their state of culture. Supposing the valuator to decide in his own mind as to the rotation, his next business is to calculate the expense and produce of the whole course and after deducting all expenses whatever and ten per cent. per annum on the capital employed, the balance may be considered as the rack-rent which such a field may afford.

3333. *In valuing a farm for rent*, each field must be valued separately in the manner above stated, and a particular rent per acre determined for each field, from which an average rent can be made out for the whole farm In some cases it is customary to value the farm buildings, dwellings, yards, gardens, &c. but when that is done a sum in proportion to their value is deducted from the supposed profits as household and other expenses, so that no advantage is gained by it. It is by means of those buildings, threshing machine, and other conveniences, that so much can be paid for each field and therefore to pay for the buildings, and pay also for their advantages, would be unjust. It must be further obvious, that a great variety of other considerations must be taken into account before even the value of a single field can be ascertained, such as distance from markets, roads, parochial and country towns, price of labour, &c. But after all, it is seldom that land is taken or let on such valuations rent, like price of every kind, depending more on the quantity of land in the market, and the number of tenants in want of farms, than

on the real value of land. Thus, indeed, often tends to the ruin of farmers, by obliging them to give higher rents than the land can bear but the same thing takes place in every other trade or profession.

3334. *The amount of the rent of lands is commonly determined in money alone but owing to the fluctuations in the value of this commodity rents are in some places made payable partly in money and partly in corn (or beef or wool in some cases), or in money, and the money value of a certain quantity of produce per acre. In some cases the money value of the produce is determined by its price in the district for the current or preceding year, and in other cases by an average of the money price for the preceding three, five, or seven years. This plan has, within the last seven years, been adopted in many parts of Scotland, and been generally approved of both by landlords and tenants. There is no plan that will in every year be perfectly equitable and for this reason many consider the money rent as on the whole the simplest and best, as it certainly is that which occasions least trouble to all parties.*

3335. *The valuation of leases well deserves the study of the culturist, and especially of the farmer who may often wish or find an opportunity of purchasing a renewal of his lease, or have occasion to dispose of an improved rent, or in other words, sub-let his farm at a profit. It is customary in many parts of the kingdom, for landlords to compound with their tenants, by accepting a sum of money paid down in place of advancing the rent at the expiration of a former or a current lease. To be able to point out the exact amount of the sum to be paid in any transaction of this nature according to the annual profit, and the number of years for which the lease is to be granted, must obviously be particularly useful. The valuation of church leases and of college lands is of not less importance, as these for the most part are let on twenty-one years leases, renewable for seven years longer at the end of every seven years or on leases for lives, every life being renewable as it drops, for a certain sum to be determined according to the age of the life to be put in, and the value of the lands.*

3336. *The principle on which all calculations as to the value of leases are made is as follows. — A sum being fixed on, which is considered or agreed on as the worth or profit which the tenant has in the lease, and the time which the lease has to run or for which it is to be renewed being agreed on, then the purchaser of the lease or of the renewal pays down to the seller the present value of an annuity equal to the profit or worth, reckoning money at its market price, or at what is called legal interest. Thus, should it be suitable to the convenience of both parties to renew a lease of twenty-one years of which only one year had expired, the tenant ought to pay the landlord 7s 2d for every pound of profit he has in the lease. Should it be asked how the tenant is to pay the landlord only 7s 2d out of each pound that he had of profit in the one year that has elapsed, it is answered that the landlord had no right to receive the 7s 2d until the expiration of twenty years, which is the number the lease has yet to run and that this sum of 7s 2d laid out at compound interest, at 5 per cent. payable yearly would, at the end of twenty years, amount exactly to 1l so that the landlord has received just the amount of what he was entitled to, and no more.*

3337. *Or, as the most customary period at which to renew during the currency of a lease of twenty-one years, is when seven years have elapsed then the exact sum that ought to be paid for adding seven years will be 2l 18s 5d. for every 1l of annual profit, because 2l 18s 5d. laid out at compound interest, will, in twenty one years, the length of lease obtained by paying it, amount exactly to 7l the profit that would have accrued to the landlord during the seven years of renewal.*

3338. *The method of determining all questions as to the renewal of leases, sale of profits on sub-leases, &c. is easily learned from the common books of arithmetic, and the value of lives from tables composed from a long series of observations in different places, as at London, Northampton, &c. But practical men can seldom have recourse to so tedious a method as calculating for themselves, by which, for want of daily practice, serious errors might be made. They therefore have recourse to published tables on the subject, by which the most intricate questions of this kind may be solved by the humblest individual who can add and subtract, in a few minutes. The tables in most repute at present are, *Baily's Tables for the Purchasing and Renewing of Leases 1807; Clarke's Enquiry into the Nature and Value of Leasehold Property and Life Annuities, with many Tables, 1806* and there is a useful pocket compendium entitled, *Tables for the Purchasing of Estates, Leases, Annuities, and the Renewing of Leases*, by W. Inwood, London 1811. There is a recent work on *The Valuation of Rents and Tillages*, by J. S. Bayldon, which is the best of its kind extant.*

3339. *The questions following, and others of similar importance to agriculturists, and indeed to all men of property, may be answered from these tables.*

*Question. If 12l sum must be paid down for a lease for twenty-one years to make five per cent. and get back the principal?*

*Answer. Twelve years and three quarters purchase of the annual rent.*

- Q. What sum ought to be paid for a lease granted on a single life aged thirty to make four per cent. and get back the principal?
- A. Fourteen years and three quarters purchase of the clear annual rent.
- Q. What sum ought to be paid for a lease held on two lives of twenty and forty years, but determinable on the death of either to pay five per cent. and get back the principal?
- A. Ten years' purchase.
- Q. What sum ought to be paid for a lease held like the last on two lives of twenty and forty years, but to continue during the existence of either of the lives, to pay five per cent. and get back the principal?
- A. Sixteen years' purchase.
- Q. What sum or fine ought a tenant to give for the renewal of four years lapsed in his lease of ten years, in order to make seven per cent. interest of his money and get back the principal?
- A. Two years and a quarters' purchase of the annual value or clear profit which he makes of the holding.
- Q. A farmer is offered a lease during the life of a person aged thirty years, to what term certain is that considered equivalent?
- A. Twenty-one years.
- Q. In a lease held originally on three lives, but of which one is dropped, the ages of the lives in possession being sixty and sixty; what sum ought the tenant to pay for passing in a new life aged fifteen, in order to make five per cent. interest and return the principal?
- A. Three years and a quarter of the clear improved rent or profit which he has in the lease.
- Q. A. has an estate in land and houses let for 100*l.* per annum. He wishes to sell the reversion of this rent after the death of his father aged sixty-five years, his wife aged forty-one, and himself aged thirty-three required the sum that must be paid by the purchaser?
- A. The father's life is worth ten years, the wife's twenty; and his own eighteen years; say twenty-one years; as the probable period at which the property will fall to the purchaser of the reversion. Thus the value to the latter is the present value of an annuity of 100*l.* a year, due twenty-one years hence. This, calculating interest at 5*l.* per cent., is 761*l.* 5*s.* and at 4*l.* per cent. 1155*l.*

3340. *In the valuation of freehold landed property* the clear annual value must first be ascertained by a minute examination of every part of the estate, and of every internal and external circumstance affecting it. An estate may be neglected, or underlet on short or long leases or overlet by means of bonuses, or favourable conditions given to the tenants or it may be burdened by parochial taxes these, and a number of other circumstances, require to be taken into consideration in determining its annual value. The annual value is often different from the annual produce and therefore in making a calculation of the sum to be paid for an estate, the difference between them forms an essential part of the data. Thus, an estate of the annual value of 100*l.* may be let on a lease of which fourteen years and a half were unexpired for 80*l.* in which case there must be deducted from the price the present value of an annuity of 20*l.* for fourteen years and a half. Thus, if twenty-five years purchase or 2500*l.* was the price agreed on, there must be deducted 900*l.*

3341. *In determining the sum to be paid for estates in perpetuity* there are no guides of universal application but the state of the market and public opinion. However, a sort of abstract principle has been laid down as applicable to this country, which it may be worth while to notice. N Kent, a land agent of much experience, says (*Hints to Gentlemen of Landed Property, &c.* 1793, p 266) "the want of a criterion to determine the price of estates creates doubt, and doubt impedes the transfer any thing, therefore that can aid the purpose of passing estates from one person to another with the greater facility may be properly introduced here." Suppose then that the gradual scale by way of an outline, be taken up thus — When the funds stand pretty steady at four per cent. the standard of mortgages may be considered at four and a half the fee simple on the nett return of land ought then to be current at three copyholds of inheritance upon a fine certain at three and a half copyholds, with a fine at the will of the lord at four. This general rule is short, and may be registered in the mind of every man of business. At the same time Kent states, that "nineteen times out of twenty, estates are bought and sold upon round numbers."

3342. *In making calculations of the value of estates, the following rules deserve notice* — In order to know the number of years purchase that ought to be given for an estate in perpetuity according to the several rates of interest which the purchaser may wish to make of his money it is only necessary to divide 100 by the rate of interest required, and the quotient will show the number of years purchase that ought to be given.

3343. *With respect to the value of freehold estates,* or the gross sum which ought to be paid for the same, Bailey observes, we may either multiply the number of years purchase, found as above, by the annual rent of the estate, or we may "multiply the annual rent of the estate by 100, and divide the product by the rate of interest which we propose to make of our money the quotient will be the sum required. For example, the sum which ought to be paid for a freehold estate of the clear rent of 90*l.* per annum, so that the purchaser may make 4 per cent. interest of his money, is found either by multiplying 25 by 90, which gives 2250*l.* for the sum required or by multiplying 90 by 100, which produces 9000, and then dividing this product by 4, which gives 2250*l.* as before. The first way is the most expeditious, where the number of years purchase is an even quantity but the latter will be found the most ready, where the number of years' purchase is a fractional quantity, or is not precisely known. Thus, the gross sum which ought to be paid for a freehold estate of the clear rent of 150*l.* per annum, in order that the purchaser may make 7 per cent. interest of his money is found by multiplying 150 by 100, which

produces 15,000, and then dividing this product by 7 which gives 2142L 17s. 2d. for the sum required now if, in answering this question, we had begun by finding the number of years purchase which ought to have been given for the same, the process would have been rendered much more tedious and intricate.

3344. In order to find the clear annual rent which a freehold ought to produce so as to allow the purchaser a given rate of interest for his money, we must "multiply the gross sum paid for the same, by the given rate of interest, and then divide the product by 100 the quotient of which will be the annual rent required" thus, if a person gives 5940L for a freehold estate, and he wishes to make  $6\frac{1}{2}$  per cent. interest of his money then 5940 multiplied by 65, will produce 38,610, which, divided by 100, will quote 386 1 or 386L 2s. for the clear annual rent required. Lastly

3345. The rate of interest allowed to the purchaser of a freehold, is much more readily and more exactly ascertained than in the case of leases for terms, as we have nothing more to do here than to "multiply the clear annual rent of the estate by 100, and then divide the product by the sum paid for the estate the quotient will be the rate of interest required" thus, if a person gives 2000L for a freehold estate of the clear rent of 85L per annum then 85, multiplied by 100, will produce 8500, which, divided by 2000, will quote 4 25, or  $4\frac{1}{4}$  per cent. for the rate of interest required.

3346. The valuation of mines and minerals is not a matter of much difficulty, when it extends merely to quarries of stone, lime, chalk, gravel, or other bodies "open to the day" or worked from the surface. If the quantity is indefinite, then the annual income afforded forms the ground-work if it is limited, then the joint consideration of the quantity, and the probable time the current demand may take to exhaust it. The valuation of metallic mines belongs to a distinct class of professions known as mineral surveyors, and is a matter foreign from agriculture, which confines itself to the earth's surface, or at least to the epidermis of its upper crust

SUBJECT. 6 Professional Routine of Land Surveyors, Appraisers and Valuers, in making up their Plans and Reports.

3347. For portraying rural objects various modes have been adopted by land surveyors trees are sometimes shown by small crosses or ciphers, triangles or dots (fig 524. a) by

an orbicular line representing the extension of the branches or head, and a dot in the place of the trunk (b and d), by the same, with the addition of a shadow taken when the sun is south or south-west, and his elevation exactly  $45^\circ$ , by which the points of the compass are readily ascertained throughout the plan and the shape of the head, and the height of the tree exhibited (e) sometimes an elevation or profile of the tree is given, either in foliage (f) or to show the form of the trunk and branches (g), or merely to give a rude idea of a tree (c). Hedgerows, whether with or without trees, are either shown in elevation or profile (h) or in vertical profile or birds-eye view (i). They may be delineated either in skeleton or foliage. Buildings may be shown either in general plan (k) detailed plan (l) vertical profile of the roof (m) elevation (n) perspective view (o) or a plan may be given (p) and a diagonal elevation (q) taken and placed opposite the plan in the margin of the map. A pictorial surveyor who understands perspective, and is desirous of conveying a correct idea of the subject he is to measure and delineate, will readily find expedients for attaining success

3348. In portraying elevations and depressions on paper, the simplest way is to introduce sections, in dotted or otherwise distinguished lines, to prevent their being mistaken for surface-lines or in wavy surfaces, figures may be introduced, thus 7 or 4, to denote their elevation above, or depression below some piece of water or other surface fixed on as a medium. Some excellent observations on this subject will be found in Major Lehman's *Topographical Plan-Drawing*, as translated by Lieutenant Sibern (oblong fol. Lond. 1822) which, it is to be hoped, will soon be appropriated in the popular books on land-surveying and adopted in practice.

3349. Where it is in contemplation to form canals, or other reservoirs or pieces of water the elevations and depressions or levels must be taken and recorded either by sections or arithmetically with the greatest accuracy and, in some cases, sections may

require to be taken, to show particular trees, buildings, the depth of water, or other objects. (Fig 525)

5250. With respect to the elevations and shapes of hills and mountains, they are only to be measured correctly by the quadrant and theodolite in the hands of regular land-surveyors. Their shape and dimensions are laid down in maps in the same manner as those of smaller deviations from the flat surface. Inaccessible dimensions of height, as of trees or buildings, are obtained by the quadrant, or by relative comparisons of shadows; of depth, as of water or wells, by rods of breadth or length, by finding the two angles of a triangle whose base shall be in one extremity of the distance, and apex in the other. These, and many other equally ample problems in trigonometry need not be enlarged on, because they must be supposed to form a part of general education.

5251. In portraying the general surface of land estates, different modes have been adopted by modern land-surveyors. The first we shall mention is the old mode of giving what may be called the ground-lines only as of roads, fences, water-courses, situations of buildings and trees. (Fig 526.) This mode has no other pretension than that of accuracy of dimensions, and can give few ideas to a stranger who has not seen the property, beside those of its contents and general outline.

5252. In the second, elevations of the objects are added to these lines but which, in crowded parts, tend much to obscure them. (Fig 527) This mode is perhaps the best calculated of any to give common observers a general notion of an estate; more especially if ably executed. Very frequently however, this mode is attempted by artists ignorant of the first principles of drawing, optics, or perspective, and without taste. The Germans who, in general, are far better topographical draughtsmen than any other people, excel in this manner and contrive, by joining to it Lehman's mode of shading the surface, to produce pictorial plans of extraordinary accuracy and beauty. The most perfect artist in this style who has ever appeared in England is Mr Hornor, whose work on the subject will be afterwards referred to. Were landed proprietors aware that their estates could be mapped in this manner almost as cheaply as by the ordinary mode, they would not rest satisfied with the meagre delineations generally made out.

5253. In the third, a vertical profile, or geometrical birdseye view that is, a birdseye view in which all the objects are laid down to a scale, is presented. In this the upper surface of every object is seen exactly as it would appear to an eye considerably elevated above it, and looking centrally down on it. (Fig 528) This mode, properly executed, is calculated to give a more accurate idea of the furniture or surface-objects of an estate than any other and if the declivities be correctly indicated, and the shade of the hollows and eminences be laid on with reference to some medium elevation, referred to or illustrated by sections taken in the direction of indicated lines (a b) it will give an equally correct idea of the variations of the ground. In short, it is the best mode for most purposes, and is now coming into general use.

528

3954 A very complete method of giving the plan of an estate, is to adopt the profile manner and include such a portion of the plans of the adjoining estates or country, as shall be contained within a circle of moderate extent (fig 529), the centre of which may

529

be the centre of the demesne lands, family mansion, or prospect tower. Around a map so formed, the distant scenery as seen from the roof of the house, or prospect tower may form a panoramic circumference, or margin of prospects (fig 529). In all these modes,

N n

dimensions and contents are given or obtainable along with effect, in all those which follow, effect or general appearance only is obtained.

3355. The *natural bird's-eye view* is intended to give a general idea of the external appearance of an estate. In this the eye of the spectator is supposed to be considerably elevated above the centre of the estate, and all the objects are portrayed exactly as they would appear to him in that situation; largest in the centre, and gradually diminishing to the circumference of the circle of vision. In such a delineation, parts of other adjoining estates may often require to be included, in order to complete the circle but these are necessary to the general idea, and can easily be distinguished from the principal property by minute marks on the delineation.

3356. In the *panoramic view*, the delineator supposes himself placed on an eminence, as the roof of the mansion where central, and looking round on all that he sees on every side. Where there is a prominent hill, or where the mansion is on an eminence, this is a very desirable mode of giving a general idea of a demesne, and by the aid of horizontal lines, and lines converging to them from the centre of vision, some idea may be had, on flat surfaces at least, of the relative heights and distances of objects.

3357. A simple mode is to give a *general view, or distant prospect*, of the estate or its principal parts (fig. 590.) as seen from some elevated conspicuous hill, building, or object near it or if the estate, as is frequently the case, is situated on the side of a hill, or range of hills, a position on the plain or flat grounds opposite to it will be sufficient.

590

3358. For the delineation of maps, the most desirable material in point of durability is parchment but where there is a chance of alterations being made on the estate, as in the lines of roads, fences, streams, &c. it is better to delineate on paper as the corresponding alterations can be made on the map with greater ease. Such colours as are stains, and do not wash out, are proper for maps and plans on parchment but where alterations may require to be made or where shadow, or any thing like picturesque effect is to be attempted, water colours alone must be used. To delineate estates and plans of every kind in a beautiful and expressive manner much depends on having the very best instruments and colours, and in knowing how to use them. The sight of good models is also an important matter and for this we may refer to Horner's elegant work, *The Art of delineating Estates*, 1813, and the very scientific work of Lehman, already mentioned.

3359. In the *writing or printing* on maps great want of taste is often displayed. No principle can be more obvious than that the name of a thing, or the ornaments of an object, should not be made more conspicuous than the thing or object itself. Yet this rule is constantly violated in plans of estates, by the large ornamental writing or print interspersed in and around them conspicuous blazonry of the name of the estate and its owner at some corner, and of the compass and scale in others. All these adjuncts should be kept in due subordination to the main delineation.

3360. Models of very mountainous estates will be found preferable to any description of maps or views, for giving a correct idea of them. Such models might be formed in plaster of Paris, wax, or various other materials, and coloured after nature. We constructed such models in 1805 (See *Farm. Mag.* vol. vi. p. 126.) and Mr Taylor of London has recently constructed them, both for the purpose of surface improvements and mineralogical examination. (See *Gard. Mag.* vol. v. p. 213.)

3361. *Reference books* are essential accompaniments to maps or models, and are of various kinds. Sometimes they merely contain the names and contents of the fields or other parts or divisions, with the state of culture or condition in which they are; in other cases the soil and subsoil are described; but in the most complete cases each farm is

described together with the history of its occupation or improvement under the following or similar heads --- Name, parish, extent, boundaries, when first enclosed, how let and managed hitherto, to whom and for how much let at present, description of the farmery and house, contents, fences, trees, ponds, soil, subsoil, surface, expense, &c. of each field number of timber trees on the farm, copse woods, and various matters. In addition to such a description as the above some add in the reference book a separate map of each farm, which renders the whole very comprehensive; and as nothing can be more interesting than the contemplation of a man's own property on all sides, and in every possible bearing, these books are generally valued above all others by country gentlemen.

3362 *The valuations of farming stock, allots, and leases*, being of temporary use, are made out with little form. In most cases, the value of particular articles is not given, but only an enumeration of them, and the sum total. The valuers have the separate values in their private memorandum books and in cases where two valuers are employed, one on each side, if an umpire is obliged to be called in in consequence of disagreement, then the parties have reference to their notes. In some cases of valuations by two parties, the umpire, being appointed beforehand, accompanies the valuator, hears their discussion on each article as it comes under review and decides any difference that may occur as they go on. This is considered the best mode, and is that generally adopted in the case of valuations made by order of the Court of Chancery.

3363 *In making up valuations for purchasing or selling estates*, a report is generally required to accompany the valuation, stating the ground on which it is made. Such a report embraces a great variety of objects according to the nature and extent of the property and ought to be drawn up in a clear and systematic manner, with such a table of contents and an index as may render it of easy reference.

3364 *In delineating buildings for agricultural purposes*, the ordinary plans, elevations, and sections, of architects and surveyors, should always be given, for the purpose of forming estimates and working plans. But for the purpose of enabling the proprietor or other person not sufficiently acquainted with pictorial effect on paper, to form a due estimate from any drawing of the effect it will have when executed, we recommend models or isometrical views. The latter in our opinion, ought to be in universal use among architects.

3365. *Isometrical perspective* is a term given recently by Professor Farish of Cambridge, to a projection

331

made in rays parallel to the diagonal of a cube upon a plane perpendicular thereto. This is a comprehensive and useful method of exhibiting the several parts of a housestead, and any person moderately acquainted with drawing, if they make the attempt, will find it extremely easy to perform; nothing more

N n 2

being required than to divide a circle into six equal parts, which may be done with the radius; and draw the hexagon and three radii, one radius to every other angle, to represent a cube (fig. 531). All the vertical or plumb lines in any design are then to be drawn parallel to  $g d$ ; all those in the direction, say north and south, parallel to  $a c$ ; and all those at right angles, or perpendicular to the last, or in the direction east and west, parallel to  $a f$ ; and the several heights, lengths, and breadths, being taken from a scale of equal parts, and set off, and lines drawn in these three directions, the projection is produced. The position of any point, or the direction of any other line, may be found, by finding where the first would fall upon any plane parallel to either of the three sides of the cube, and where the latter if produced, would cut any line in the three directions. (*Wheatell's Designs*, &c. p. 51.) The elevation which thus mode of drawing produces is highly explanatory and expressive (fig. 531).

## BOOK II Operations of Order and Management

3366 *The business of agriculture*, whether in the management of extensive estates or the culture of single farms, requires to be conducted in an orderly and systematic manner. For this purpose a certain establishment of operators, a certain style of books of accounts, and great attention in all commercial transactions, may be considered the fundamental requisites.

3367 *The establishment of co-operators and servants* must depend on the extent of the subject of management. An extensive landed estate, which, in addition to farming lands, contains woods, quarries, mills, mines, waters, manorial rights, game, and villages, will require a series of subordinate managers but in general a steward as a head manager a steward's clerk or assistant, and in some cases a local steward, are all the managers requisite the subordinate care of quarries, woods, game &c. being performed by a quarryman, forester gamekeeper, or by common servants of tried fidelity.

3368 *The gradation of operators required on farms* depends on their size. Whenever the master does not labour himself a foreman or operator having some charge is requisite and in very extensive cases, where there is a considerable extent of grazing ground as well as tillage lands, a head ploughman and a head herdsman will be found advantageous. There should also be a confidential labourer or *headman of all work* to superintend and accompany women and children in their operations, as in hoeing, weeding, planting potatoes, &c. The grand point to be aimed at by the steward of an extensive estate, and the occupier of a large farm, is to hit on the proper number of sub-managers and to assign each his distinct province, so that the one may never interfere with the other. Having attained this, the next thing is to keep the whole machine in regular action to keep every man from the lowest operator to the highest, strictly to his duty. All operators ought to be adequately remunerated and it is better in general to pay a liberal price and require vigilant, skilful, and active exertion, than to cheapen labour and so encourage indolence and bad execution. For the lower class of labourers, especially such as are hired by the year it will often be necessary to attend as well to the food they eat, as to their constancy at work. In the case of farm servants, for example, it will generally be found preferable to board and lodge single men than to substitute a sum of money which they will in many cases either save or spend otherwise than so as to strengthen their bodies. Where labour is done by the job, all that is requisite is to see that it is done well, and according to agreement and thus, as we have already observed, is the best mode wherever it can be adopted.

3369 *Orderly conduct in the lower classes of workmen* is a point to which we would wish particularly to direct the attention of the bailiff and farmer. Regularity in their hours neatness and cleanliness in their dress punctuality in cleaning and putting away in the proper places their implements of labour or harness humanity to working and other animals decency in general deportment and conversation, and ambition to excel in their particular department. Neatness and order whether on an estate, a farm, a stable, a dwelling house, or in a man's dress and manner form an index to every thing else. Estates and farms where these qualities prevail, are always well-managed and cultivated a neat and clean stable is a sure sign of well-conditioned horses, and of economical feeding a dwelling-house, with neatness around and within, is an index of comfort and peace and a decently dressed and well behaved man or woman is sure to be approved in every station.

3370 *The necessity of order and neatness* we are most anxious to impress on the minds of all descriptions of masters and managers. Order it has been well observed, is "Heaven's first law." It is, indeed, the end of all law without it, nothing worth having is to be attained in life, even by the most fertile in resources and with it, much may be accomplished with very slender means. A mind incapable of an orderly and regular disposition of its ideas or intentions will display a man confused and disorderly in his actions he will begin them without a specific object in view continue them at random, or from habit, without knowing well why till some accident or discordant result puts an end to his present progress, numbs him for life, or awakens reflection. But a well-ordered mind considers, arranges, and systematises ideas before attempting to realise them weighs well the end in view considers the fitness of the means for attaining that end, and the best mode of employing these means. To every man who has the regulation and disposal of a number of servants, this mode of orderly arrangement is essentially necessary in order to reap the full effects of their labours; and to no man is it

of more importance than to the agriculturist, whose cares are so various, and the success of whose operations, always connected with and dependent on living beings, depends so much on their being performed at the fitting moment.

3371 *Propriety* relates to what is fitting and suitable for particular circumstances: it is the natural result of an orderly mind, and may be said to include that part of order which directs the choice and adaptation of means to ends, and of ideas and objects to cases and situations. It belongs to order for a master to allow workmen proper periods for rest and refreshment: propriety dictates the time and duration of these periods, and prudence suggests the wisdom of departing as little as possible from established practices. Decorum is the refinement of propriety.

3372 *Neatness*, as opposed to slovenliness, is well understood: it consists in having every thing where it ought to be, and in attending to the decorum of finishing operations, and to minute things in general.

3373 *As maxims of order and neatness* which ought to be continually present to the minds both of masters and servants, we submit the following:—

3374 *Perform every operation in the proper season.* The natural, and therefore the best, indications for the operations of sowing and reaping, transplanting &c. are given by the plants themselves, or by the progress of the season as indicated by other plants. There are artificial calendars, or remembrancers, the use of which is to remind the master of the leading crops and operations of culture and management throughout the year: but, even if such books were made as perfect as their nature admits of, still they are only calculated to aid the memory: not to supply the place of a watchful and vigilant eye and habits of attention, observation, reflection, and decision. Unless a steward or farmer has these, either naturally or partly from nature and partly from cultivation in a considerable degree, he will be but little better than a common labourer as to general management and culture.

3375 *Perform every operation in the best manner.* This is to be acquired in part by practice and partly also by reflection.

3376 *Complete every part of an operation as you proceed.* This is an essential point in field operations: and though it cannot always be attended to, partly from the nature of the operation, partly from weather &c., yet the judicious farmer or bailiff will keep it in view as much as possible.

3377 *Finish one job before you begin another.* This advice is trite, but it is of great importance: and there are few cases where it cannot be attended to.

3378 *In leaving off working at any job, leave your work and tools in an orderly manner.*

3379 *Attend strictly to the hours of commencing labour and equally so to those of leaving off, unless extraordinary exertion is required.*

3380 *Whenever extraordinary exertions are required extraordinary indulgences or rewards must be given as compensations.*

3381 *A regular system of accounts* is an obvious part of order and correctness: and it is equally obvious that the extent to which this must be carried will depend on the subject of management. In the case of extensive landed estates, the regular set of books usual in mercantile concerns becomes requisite: with the addition of some, as a forest-book, time book, &c. rendered necessary by particular departments of the subject. On small farms, on the other hand some memorandum-books, a cash-book, and a ledger are all that will be found necessary. Our business here is to give the form of the time-book, which is or may be common to every department of agriculture and scale of management, though most necessary for bailiffs, where a number of day labourers are employed on improvements. In giving the practice of the different branches of agriculture, the books peculiar to each will be described. There is nothing indeed, that should be more strenuously pressed upon the attention of farmers, than the importance of a good system of keeping their accounts, in which they are, generally speaking, very deficient.

3382 *The time-book* is a large folio volume, ruled so as to read across both pages, with columns titled as in the specimen annexed. In this the bailiff or master inserts the name of every hand: and the time in days, or proportions of a day which each person under his care has been at work, and the particular work he or she has been engaged in. At the end of each week the bailiff or master sums up the time from the preceding Saturday or Monday to the Friday or Saturday inclusive: the sum due or to be advanced to each man is put in one column, and when the man receives it he writes the word *received* in the column before it, and signs his name as a receipt in the succeeding column. The time-book, therefore, will show what every man has been engaged in during every hour in the year for which he has been paid, and it will also contain receipts for every sum, however trifling which has been paid by the bailiff for rural labour. In short, it would be difficult to contrive a book more satisfactory for both master and servant than the time-book, as it prevents, as far as can well be done, the latter from deceiving either himself or his employer, and remains an authentic indisputable record of work done, and of vouchers for money paid during the whole period of the bailiff's services.

## PART III

## AGRICULTURE AS PRACTISED IN BRITAIN

3385 In the first Part of this work we have endeavoured to give a concise view of the actual state of agriculture in every country with a view to interest the reader in the subject, and prepare him for entering in detail on the elementary principles of the art. In the second Part, these principles and elementary departments of agricultural knowledge have been developed in successive views of the nature of vegetables, animals, and soils, and the mechanism and science of agricultural implements and operations. As far as these elementary principles go, they are applicable to the agriculture of every part of the world, with the modifications required by different physical and geographical circumstances, but as such an application is not required, in a work designed principally for this country we limit this part of our work to the agriculture of Britain, in its most improved mode of practice. In the extensive sense in which we have applied the term Agriculture, this will include, 1st, the valuation, purchase, and transfer of landed property 2d, its laying out, or arrangement 3d, its improvement and 4th, its management 5th, the hiring and stocking of farms 6th, the culture of farm lands, and 7th, the economy of live stock and the dairy

## BOOK I

## OF THE VALUATION, PURCHASE, AND TRANSFER OF LANDED PROPERTY

3386 On the existence of property depends all human improvement Personal property is the first acquirement of man but scarcely any progress is made in civilisation till property in land is established and rendered secure. Landed property indeed, is the basis on which every other material property is founded, and the origin from which it has sprung The landed estates of Britain, as a species of property, may be considered in regard to tenure, valuation, and transfer

## CHAP I

*The different Kinds and Tenures of Landed Property in the British Isles.*

3387 As landed property is somewhat different as to tenure in the three kingdoms, we shall notice the leading features in each separately

SECT I *The Kinds of Landed Property and its different Tenures, in England.*

3388 *Territorial property in England*, Marshal observes, aptly separates into two principal divisions — namely into possessory property or the actual possession of the lands and their appurtenances and into abstract rights arising out of them.

3389 *Possessory property* comprises the soil or land itself the minerals and fossils it covers the waters annexed to it the wood and herbage it produces and the buildings fences &c. thereon erected.

3390. *Abstract rights* are, seigniorial, as chief rents, &c manorial, as quit-rents, fines, &c. prescriptive, as common rights predial, as tithes parochial as taxes.

3391 *Advison and parliamentary interest* might be added, as they are not unfrequently attached to landed property

3392. *Possessory property is further liable to analysis*, and to more particular distinctions.

3393 *Freehold*. If lands are held unconditionally and in full possession, without any other superior than the constitution and laws of the country, they are termed *freehold*; a term which admits of still further distinctions.

3394 *Feefarmhold*. If they are liable to regular and fixed annual payments, beneath their rental value, and without being liable to fine, heriot, or forfeiture, they are *feefarmhold*, or other inferior holding

"particular" of the estate on sale; showing, or which ought to show, not only the aggregate quantity but the number of acres that each piece or parcel contains and ought, most particularly to specify the distinct quantities of the lands of different qualities, in order that their several rental values may with greater accuracy and ease, be ascertained.

3415 *The intrinsic quality of the land* is another essential basis of calculation. But even this, in a general view of the value of lands throughout the kingdom, is often of secondary consideration for in many cases, their values are given by situation, rather than by soil and substrata. In some cases, as has been already said, the value of the situation may be fivefold that of the intrinsic value of the land. This excessive influence of situation, however is limited in its effects, and is chiefly confined to the environs of towns, and other extraordinary markets for produce a great majority of the lands of England owe their values less to situation than to intrinsic quality, and to come at this, with sufficient accuracy is the most requisite, and, at the same time, the most difficult part of valuation, as it depends almost wholly on extemporary judgment, exercised on the frequently few data which rise to the eye in passing over the field of estimation. It is almost needless, therefore, to observe, that, to acquire the degree of judgment necessary to this critical task, it is requisite to know the productiveness of lands of different appearances a species of knowledge which scarcely any thing but mature practice, in the cultivation of lands of different qualities, can sufficiently teach though long habit may do much, in ordinary cases, towards hitting off the value of lands without an extensive knowledge of the practice of agriculture. There are, however, cases in which we find both of these qualifications insufficient to give an accuracy of judgment, even among provincial valuers and a man who ventures to step forward as a universal valuer, should either have an extraordinary talent for his line of profession, or should after a suitable initiation, have had great experience in rural concerns in various parts of the kingdom.

3416 *On situation*, the value of lands, aggregately considered depends less, than on intrinsic quality though, without doubt, situation has great influence. Thus, land whose intrinsic quality renders it, in an ordinary situation, worth twenty shillings an acre, would not, in some districts, be worth more than fifteen shillings while in others it would bear to be estimated at twenty-five shillings, or a higher rent, to a farmer on a large scale, and away from the immediate environs of a town or any populous district of manufacture for reasons that will appear in examining the different particulars of situation.

3417 *In the temperature of situation*, whether it is given by elevation aspect, or exposure, we find a powerful influence which is capable of altering exceedingly the value of lands. The same soil and sub-soil, which we not unfrequently see on exposed mountains, and hanging to the north and which in that situation are not worth more than five shillings an acre, would, if situated in a sheltered vale district, and lying well to the sun, be worth twenty shillings, or a greater rent. Even on climate, something considerable depends. In the south of England, harvest is generally a month earlier than in the northern provinces though it is not regulated exactly by the climate or latitude of places, a circumstance that requires to be attended to by those who estimate the value of estates for an early harvest is not only advantageous in itself but it gives time to till the ground or to take an autumnal crop, which are advantages that a late harvest will not so well admit of. And another kind of temperature of situation has still more influence on the value of lands, namely the moistness of the atmosphere. A moist situation not only gives an uncertain and often a late harvest, but renders it difficult and hazardous, as too frequently experienced on the western coasts of this island.

3418 *Even in the form of surface* we find exercise for the judgment. Lands lying with too steep or too flat surfaces, especially recently arable lands are of less value than those which are gently shelving, so as to give a sufficient current to surface water without their being difficult to cultivate. Steep-lying lands are not only troublesome and expensive, under the operations of tillage, but in carrying on manures and getting off the produce. Lands lying with an easy descent, or on a gently billowy surface, may be worth more by many pounds an acre, purchase money than others of the same intrinsic quality hanging on a steep.

3419 *A supply of water for domestic purposes*, for the uses of live stock, and for the purpose of irrigation, is another consideration of some weight in valuing an estate. There are situations in which a copious stream of subterranean water would enhance the fee-simple value of a large estate some thousand pounds.

3420 *A sufficient supply of manure*, whether dung, lime, marl, or other melioration, at a moderate price, and within a moderate distance of land carriage, materially adds to the intrinsic value of lands.

3421 *The established practice of the country* in which an estate lies, is capable of enhancing or depressing the value of it exceedingly. Even the single point of practice of ploughing light and heavy lands with two oxen, or two active horses, instead of four heavy ones, is capable of making a difference on good land, which is kept alternately in herbage and corn crops, of five to ten shillings an acre a year; or ten pounds an acre purchase money.

3422 *The price of labour* is another regulator of the marketable price of land in a given district. It is always right, however to compare this with the habits of exertion and industry which prevail among farm workmen, before the net amount of labour can be safely set down.

3423 *The price of living or expense of housekeeping* prevalent among farmers, has its share of influence on the value of lands. In the more reclusive parts of the north of England, farmers and their servants are fed, clothed, and accommodated, at nearly half the expense of those of a similar degree in many parts of the more central and southern provinces. It is not here intended to intimate how husbandmen their servants, and labourers, ought to live. As they are the most valuable members of the community they are well entitled to such expenditures as are compatible with care and labour. All that is meant in stating this fact is to convey a hint to the purchasers of estates. For, in a country where frugality prevails, lands of a given quality will ever bear a higher rent than they will where a more profuse style of living has gained a footing. Rent is higher in proportion to the gross produce, on the small farms in Ireland, and the west of Scotland, than in other parts of the united kingdom and yet the landlord is seldom a gainer

as such rents are not so regularly paid, and the tenant, having no reserve of capital, is in bad seasons often unable to pay any rent at all.

5424. *The spirit of improvement, or the prejudice against it, which prevails in a district of sale, is a circumstance of some value to a purchaser: for if the former is in a progressive state, especially if it is still in the earlier stages of its progress, a rapid increase of rent may with a degree of certainty be expected; whereas, under the leaden influence of the latter half a century may pass away before the golden chariot of improvement can be profitably put in motion.*

5425. *In markets, more than in any other circumstances, we are to look for the existing value of lands. Their influence is not confined to towns and populous places of manufacture for in ports, and on quays, whether of inlets, estuaries, rivers, or canals, markets are met half way; even by good roads, their distance from the farm-yard may be said to be shortened.*

5426. *In this detail of the particulars of situation, with respect to the value of landed property we perceive the attentions requisite to be employed by a valuer who is called upon to act in a country that is new to him. A provincialist, or even a professional valuer who acts in a district, the existing value of whose lands he is sufficiently acquainted with, determines, at sight and according to the best of his judgment, on their respective values for he knows, or ought to know, their current prices what such and such lands let for in that neighbourhood what he and his neighbours give, or would give for lands of the same quality and state, without adventuring to the particular circumstances of situation (they being given, in the established current prices which have arisen out of these circumstances) resting his judgment solely on the intrinsic quality and existing state of each field or parcel as it passes under his eye. But let his skill be what it may, in a country in which he has acquired a habit of valuing lands, he will, in a distant district, the current market prices of whose lands may be ten twenty or fifty per cent. above or below those which he has been accustomed to put upon lands of the same intrinsic qualities and existing states, find himself at a loss, until he has learnt the current prices of the country, or has well weighed the circumstances of situation to which in every case, he must necessarily attend, before he can determine their value under an unproved practice, or venture to lay down general rules for their improvement.*

5427. *The existing state of lands, or the manner in which they lie, at the time of sale, is the next class of circumstances which influences their marketable value.*

5428. *Their state with respect to enclosure is a matter of great consideration. Open lands, though wholly appropriated and lying well together are of much less value, except for a sheep walk or a rabbit warren, than the same land would be in a state of suitable enclosure. If they are disjointed and intermixed in a state of common field, or common meadow their value may be reduced one third. If the common fields or meadows are what is termed Lammas land, and become common as soon as the crops are off, the depression of value may be set down at one half of what they would be worth, in well fenced enclosures, and unencumbered with that ancient custom. Again the difference in value between lands which lie in a detached state, and those of the same quality that lie in a compact form is considerable. The disadvantages of a scattered estate are similar to those of a scattered farm. Even the single point of a want of convenient access to detached fields and parcels is, on a farm, a serious evil. And it is on the value of farms that the value of an estate is to be calculated.*

5429. *The state of the roads whether public or private, within an estate, and from it to the neighbouring markets, or places of delivery of produce, is an object of consideration to a purchaser.*

5430. *The state of the watercourses or shores and ditches, within and below an estate, requires to be examined into, as the expense of improvement or reparation will be more or less, according to their existing state at the time of purchase or perhaps, by reason of natural causes, or through the obstinacy of a neighbour and the defectiveness of the present laws of the country in this respect, the requisite improvement cannot be effected at any expense.*

5431. *The state of drainage of lands that lie out of the way of floods or collected water requires to be taken into consideration for although the art of draining is now pretty well understood, it cannot be practised, on a large scale, without much cost.*

5432. *The state of the lands as to tillage and manure, is entitled to more regard than is generally paid to it in valuing them. But even to a purchaser and still more to a tenant for a term, their state, in these respects, demands a share of attention. Lands that are in a high state of tillage and condition, so as to be able to throw out a succession of full crops, may be worth five pounds of purchase money an acre more than those of the same properties, which are exhausted by repeated crops, and lie in a useless state of foulness, from which they cannot be raised, but at a great expense of manure and tillage.*

5433. *The state, as to grass or arable, is better understood, and generally more attended to. Lands in a state of profitable herbage, and which have lain long so, are not only valuable, as bearing a high rent while they remain in that state but after the herbage has begun to decline, will seldom fail to throw out a valuable succession of corn crops. Hence, the length of time which lands, under valuation, have lain in a state of herbage, especially if they have been kept in pasturage is a matter of enquiry and estimation.*

5434. *Lastly, the state of farm buildings and fences is a thing of serious consideration. Buildings, yards, and enclosures that are much let down, and gone to decay for want of timely reparation, incur a very great expense to raise them again to their proper state. And when great accuracy of valuation is called for, as when the purchase value of an estate is left to reference, and when the tenants are not bound, or if bound are not able, to put them in the required state, it becomes requisite to estimate the expense which each farm, in that predicament, will require to put it in sufficient repair, so as to bring the whole into a suitable state of occupation. And the same principle of valuation holds good in ordinary purchases.*

5435. *Deductions encumbrances and outgoings, are leases, tithes, taxes, fixed payments, repairs, and risks.*

5436. *Leases* In considering the nature of leasehold tenures, it appears that, by a long lease, the fee-simple value of an estate may be, in effect, annihilated. Even a lease for years, with a mere conventional rent, may reduce it to nearly one third of its fee-simple value and every other kind of lease, if the rent payable be not equal to the

fair rental value at the time of sale, is an encumbrance, even to a purchaser who has no other object in view than that of securing his property on land, and receiving interest, in rent, for the money laid out. If personal convenience be immediately wanted, or improvements required to be made, a lease, though the tenant pay a full rent, becomes an obstacle to the purchase.

3437 *Tithes.* If in valuing lands they are considered as tithe free, the tithe, or modus, if any, requires to be deducted as an encumbrance, and seeing the great variation in the values of tithes and moduses, according to customs and plans of occupation, it is the plainest way of proceeding, to value all lands as free of tithe, and afterward to make an allowance for whatever they may be estimated to be worth. An allowance which, in some cases, as on corn-land estates, forms a considerable portion of the fee-simple value of the lands while on grass-land estates, especially such as are pastured by cattle, this encumbrance, so galling to the corn grower is in great part avoided.

3438 *Taxes.* Although it may be called the custom of England for proprietors to pay the land tax and the occupier all other taxes, yet this is not the universal practice. Nor is it, in valuing an estate on sale, and to be let at will, a matter to be enquired into. The annual amount of the payable taxes and other outgoings is the fact to be ascertained for whosever discharges them, they come as a burthen upon the gross value of the lands, out of which they are payable. For if a tenant pays them, his rent is, or ought to be, estimated and fixed accordingly. If, however an estate on sale is already let under lease for a term to come, it is highly requisite to ascertain what parts of the annual outgoings and repairs are discharged by the tenants, and what the proprietor will be liable to, during the term to run. The land tax, where it still exists, is extremely uncertain as to its value, and the poor tax is equally variable in different situations. The church, highway, and county rates are, taking them on a par of years, less liable to local uncertainty, and are consequently less entitled to enquiry from a valuer.

3439 *Fixed payments, or rent charges,* such as chief rents, quit rents, annuities, endowments, schoolmasters salaries, charitable donations, &c. to which an estate is liable also.

3440 *Repairs of public works, buildings, roads, &c.* incumbent on the estate on sale, are subjects of enquiry and estimation as well as the ordinary repairs above noticed. And, moreover

3441 *The hazard, or risk,* which naturally or fortuitously attends the lands under valuation, as that of their being liable to be inundated in summer or to be torn away by floods at any season, is entitled to mature consideration for although these evils may generally be remedied by river breaks and embankments, the erecting of these is mostly attended with great expense and the estimated value of this becomes, of course, a fair deduction.

3442 *Appurtenant to an expensive estate* there are generally other valuable considerations besides the purchase value of the lands. These are,

3443 *Minerals and fossils,* whether metals, fuels, calcareonities, or grosser earths.

3444 *Waters,* whether they are valuable for fisheries, decoys, mills, domestic purposes, or the irrigation of lands.

3445 *Timber,* of woods and hedgerows.

3446 *Buildings* that are not let with the farms, but which bear rent, independent of the lands; yet which, when scattered over an estate, may well be considered as belonging to landed property.

3447 *The estimated value of evident improvements.*

3448 *The abstract rights* which arise out of appropriated lands, or their appurtenances as

3449 *The right of commonage* which is generally of some value even when commons lie open, and may be of more value than they shall be enclosed, provided the out of enclosure do not turn out to be more than the extra value of the appropriated lands, above that of the common right in their open state.

3450 *The right of superiority* to fee-farm rents, or other chief rents, payable to the possessor of the lands on sale, out of the lands of other proprietors. These rents, though small, are of certain value in themselves and the idea of superiority which they convey to some men's minds may be worth more than the pecuniary value; which, indeed, where the sums are very small (as is often the case), is much lowered by the expense of collecting them. Besides the trouble, vexation, private quarrels, and lawsuits they are liable to excite, when, through neglect, they are half forgotten, and the vassal is willing to catch at the circumstance, to try to get rid of the teasing and humiliating encumbrance. This however may serve to account for their having been handed down with reverential care, through a succession of ages until, in many instances, even their origin, and much more the circumstances attending it, are difficult or impossible to trace. But, surely a man of a liberal turn of mind, who has no interest in legal contests, and who professes solid gold to a trinket, would not hesitate to collect these watered wrecks of property, and to convert them to a more civilised, rational, and profitable purpose. On the other hand, any man of an independent spirit would pay more than a fair price—would pay liberally—to be exonerated from so base a burthen. If, however, a vassal's chains lie easy upon him, let him wear them. What is here meant to be intimated is, that he ought to have, in liberality if not in law a fair opportunity of throwing them off.

3451 *The rights of feudality, or manorial rights,* are at present, if not in their origin, very different from those last mentioned. In the day of their establishment, they appear to have been founded in wisdom and a degree of political necessity; and, by the extracting land of them, they arrived at a high degree of

political perfection. The simple and easy mode of transferring property, which the feudal system established, was well adapted to the illiterate age in which it had its rise. Even in these latter days, and among the ruins of feudal rights, the copy of a court-roll is considered as the clearest title a man can have to his possession! What a hint is this to modern legislators! The value of feudal rights is to be estimated by the quit rents, fines, heriots, escheats, and amercements, which long customs and a train of circumstances have attached to the great court. and besides what relates to the appropriated lands of the manor the lord has a profit arising from the commonable lands (if any he within it) as lord of the mill, which cannot be broken without his permission. Hence the fossils and minerals, which it covers, belong to him as well as the timber which grows upon the waste, and the waters that are annexed to it. He is moreover in ordinary cases, lord of the game which inhabits or strays upon this manor. This, however being a right of pleasure, rather than of profit, has no fixed standard of estimation.

3452. *The right of tithes*, when attached to an estate, is the most desirable of abstract rights arising out of landed property for as far as the right extends (whether to a lay rectory or a vicarial impropriety) the lands which it covers become, in effect, tithes free as every judicious proprietor incorporates the rents of the tithes with those of the lands out of which it is payable, thus (if the right, as it generally is, be rectorial) freeing them wholly from the encumbrance of tithes, as a tax on improvements, and as an obstacle to the growth of corn. The value of tithes, as has been intimated, is so various, that nothing but local information can enable a valuer to estimate them with sufficient truth.

3453. *The right of advowson*, or the privilege of appointing a pastor to propagate religion and morality upon an estate properly enough belongs to its possessor as no other individual is so intimately concerned in the moral conduct of its inhabitants.

3454. *The right of representation or election*, or the appointment (in whole or in part) of a legislator to assist in promoting good order in the nation at large, equally belongs to the owner of territorial surface.

### CHAP. III

#### *Purchase or Transfer of Landed Property*

3455. *In bargaining for an estate* there are two methods in use the one by public bidding, and the other by private treaty. In either a certain degree of caution is requisite and in both an accurate valuation is the best safeguard.

3456. *Among the preliminaries of purchase by private contract*, the particulars which may be required to be furnished by a seller are first to be enumerated. These are the quantities of the several pieces of the lands on sale, together with the maps, or rough drafts of the same the tenure under which they are holden some assurance as to the title of the seller and his right of alienation the tenancy under which the several farms are let and, if on lives, the ages of the nominees if for a term of years the number unexpired if at will, the notices (if any) which the tenants have had.

3457. *An abstract of the covenants under which they are let*, particularly of those which relate to taxes and repairs, to the expenditure of produce, to the ploughing of grass lands, &c.

3458. *The existing rents and profits receivable*, whether for tenanted lands, appurtenances, or abstract rights with the estimated value of the demesnes, and the woodlands in hand together with the estimated value of the timber growing upon the estate on sale, as well as of the minerals and fossils which it may contain the outgoings to which the estate is liable the proposed time of the delivery of possession the price, and the mode of payment expected.

3459. *The particulars of instruction to be given to a surveyor*, or other valuer, of an estate to be purchased, may next be particularised. It will be right, however to premise, that much in this respect, depends on the probability of purchasing, and on the time allowed for making the estimate.

3460. *In cases of sale by public auction*, where there can be no certainty as to purchase, and where the time for valuation is limited, a rough estimate of each farm, and a general idea of the value of the timber and other appurtenances, may be all that can be prudently ascertained.

3461. *But, in a sale by private contract*, where the refusal of an estate is granted, and time allowed for deliberate survey a more minute investigation may be proper, especially when there is every reason to believe that a bargain will take place. For the same report will not only serve as a guide to the purchase, but will become a valuable foundation on which to ground the future management of the estate. For these, and other reasons, a purchase by private contract is most to be desired, by a gentleman who is not in the habit of personally attending public sales, and is unacquainted with the business of auction rooms.

3462. *The particulars to be required from a surveyor*, or surveyors, are principally these the rental value of each field or parcel of land, with the state in which it lies, as to arable, meadow, pasture, or woodland the value of the timber and other appur-

tenancies; the characteristics, and the state of management, of each farm or tenement, with the eligibility of its occupier, together with the state of repair of buildings, gates, fences, watercourses, and roads the amount of the encumbrances and outgoings and, lastly, the probable value of the improvements of which the estate may appear to be capable, whether by ordinary or extraordinary means.

3463. *The subjects of treaty* after these particulars of information are procured are few. The two statements having been duly compared, so that no misunderstanding can take place between the parties, the price, with the times and mode of payment, are the principal matters of agreement. A clear understanding respecting the custody of title deeds, and the expenses of conveyance, require, however to be enumerated among the preliminaries of purchase.

3464. *The business of negotiation* is best carried on by letters, which become vouchers of facts. Whatever is done by interview requires to be reduced to writing, and to be read by, or to, the parties, before they separate, that no possibility of misconception may arise, and, added to these precautions, it is proper, in large purchases, and when abstracts of intricate title deeds are to be made out and examined, that a legal contract, or memorandum of agreement, should be entered into, for the mutual satisfaction and surety of the parties.

3465. *This contract, and the deed of conveyance* (namely, the instrument which is legally to transfer the property from the seller to the purchaser) may be said to conclude and ratify the business of purchase; and in this part of it legal assistance is essentially necessary to examine existing deeds, and see that the seller has a legal right and clear title to the land, and a legal power to dispose of it, as well as to draw up or examine the fresh deed of conveyance, and see that it is sufficient to transfer the property legally and adequately to the purchaser.

3466. *The preservation of titles* may be adverted to before dismissing this subject. In Scotland, deeds of conveyance and other deeds are registered in one magnificent building, whose internal economy is as admirably adapted to its design, as its outward form is beautiful; and, in England, there are two counties (Yorkshire and Middlesex) which are termed register counties in which abstracts of deeds are preserved, and so arranged as to be readily referred to. Hence, in cases where the original deeds are destroyed or lost, these registered abstracts are sufficient evidences of their having existed, and capable of securing the titles of estates to their rightful owners, and are moreover valuable, in preventing fraudulent practices, particularly respecting mortgages. Never theless, the other counties of England remain, from reign to reign, destitute of these advantages.

## BOOK II

### OF THE LAYING OUT, OR GENERAL ARRANGEMENT OF LANDED ESTATES.

3467. *The laying out of an extensive landed estate* embraces a variety of subjects, and requires extensive information and enlarged views of political agricultural, and even of moral improvement. In new countries, such as America, where an estate is laid out from a state of nature, this is more particularly the case but the observation will also apply to many parts of the British Isles, where estates, long since appropriated, require re-arrangement and improvement.

3468. *Among the different objects of attention* in laying out or re-arranging a landed estate, one of the first is its consolidation, or the rounding off or simplifying the outline so that the whole may be brought into a compact form. This *enle de s'arrondir* seems to have existed, and the proximity and intermixture of property to have been felt as an evil by landed proprietors, in all ages. Ahab desired the field of Naboth, because it was near to his house and Marvel, the attorney (*Mansinger's New Way to pay Old Debts, &c.*) advised his client to "hedge in the manor of Master Prugal," because says he, 'his land, lying in the midst of yours, is a foul blemish.'

3469. *In consolidating property in Britain*, an equally desirable object is the appropriation of commonable lands, which, in England, can only be effected under the authority of a special act of the legislature, but is accomplished with less difficulty in Scotland, and is rarely necessary in Ireland. It is believed, indeed, that there are now no commons in Scotland, unless, perhaps, one or two belonging to the crown or the church, which cannot be divided by the general law, but must be done either by consent of parties or a special act of parliament. (C.)

3470. *The arrangement of the interior of an estate* naturally follows the determination of the ring-fence, and the complete possession of all that is within. Here the first thing

will probably be to determine the demesne lands, or site of the proprietor's residence, and the extent of territory he means to attach to it and retain in his own occupation. Then follows the intersection of the estate with roads, and probably a canal; the choice or determination of the sites for towns, villages, manufactories, and mines, mineral quarries, or fisheries, if such exist naturally. Lastly, the grounds to be planted being determined on, the remaining part of the property will consist of the lands to be let out for cultivation by farmers, or other tenants of the soil. In conformity with this view of the subject, we shall consider in succession, the consolidating of estates, the appropriating of commonable lands, the choice of demesne, road-making, canal-making, the establishment of villages and manufactories, the working of mines and quarries, the establishment of fisheries, the formation of plantations, the planting of orchards, and the laying out of farms and farm-lands.

## CHAP. I

### *Consolidating detached Property*

3471 *The advantages of a compact estate over one whose lands lie scattered and intermixed with other men's properties are evident. The management, whether of detached farms as parts of an estate, or scattered fields as parts of a farm, is conducted with inconvenience, besides the unpleasant alterations to which intermixed lands are liable to give rise. The different methods of compressing landed property into the required state are by exchange, by purchase, and by sale.*

3472 *Where the lands of two proprietors lie intermixed with each other, an amicable exchange is the most eligible, and were it not for the childish piques and petty jealousies which so frequently take root between neighbouring proprietors (and are cherished perhaps by their officious friends) lands of this description could not long exist the evil in almost any case, being easily removed. Each party having chosen one, or in extensive concerns, two referees, and the two or four so chosen, having named a third or fifth, the required commission is formed, and bonds of arbitration being signed, the commissioners proceed, as under an act of appropriation of commonable lands, to assign each proprietor his rightful share, in the most profitable situation which the given circumstances will permit. This mode of proceeding might be adopted by the most distant parties, or the most inveterate enemies, and, doubtlessly, with advantage to the property and peace of mind of each.*

3473 *Where an estate or a farm is dysnomied by the intermediate lands of others, it is not only pleasurable to be possessed of them, but profitable to purchase them, even at a higher price than they are intrinsically worth, consequently at much more than their value, as detached lands, to their proprietor. Yet such is often the waywardness and ill-judged policy of the holders of lands so situated, that they will rather continue to hold them with disadvantage, than sell them at a fair price. An equitable way of determining a matter of this sort is, to ascertain the value of the lands to the holder as detached lands, and likewise their value to the candidate as intermixed lands, and to let the mean between the two values be the selling price. By this method, both parties become actual and equal gainers. If the possessor of such lands should be in wait for an exorbitant offer, the most efficient mode of proceeding is to offer a high number of years purchase on their fair rental value, indifferently considered, in the situation in which they lie, and to propose to settle such rental value by arbitration. This is a sort of offer which every honest man can readily understand, and if the holder has any character to lose in his neighbourhood, he cannot refuse it. If he has not, a calculation of the difference between the rent he is receiving and the interest of the money offered, consequently of the annual loss which he is sustaining by not accepting the offer, will, sooner or later, bring him to a sense, if not of his duty as a member of society, at least of his own interest.*

3474 *It is, in general, right management to dispose of the detached parts of an estate, and to add to the main body. The whole is then more easily superintended, and managed at less expense, while small properties, if suitable steps be taken, and proper seasons of disposal caught, will generally fetch more than larger parcels, of equal rental value, timely and judiciously purchased.*

3475 *In selling, as in purchasing estates, two methods present themselves. They may be sold by auction or by private contract. To raise a sum of money expeditiously the former may be the most eligible, though attended with more expense and more noisiness than the latter, which, for the purpose under view, and when expedition is not necessary, will generally, if properly conducted, be found preferable. To conduct a sale of detached lands with judgment and reputation, the first step is to have them deliberately*

valued by at least two men of character and ability, and to divide them into parcels or lots, according to situation, and so as to render them of superior value to adjacent proprietors. Then fix upon each parcel such value as it is fairly worth to the owner of the lands with which it is naturally united and give him the refusal of it. Such parcels as are not disposed of in this way may either lie open to private contract, or be sold by public auction, the motive for selling being, in every case, openly declared. It is to be remarked, however that for a sale by auction, a fresh arrangement of lots will be required, the principle of allotment being in this case the reverse of the former. At an auction, a certain degree of competition is requisite to raise the article on sale to its full value and it is no more than common prudence in the seller to make up his lots in such a manner as will bring together the greatest number of competitors.

## CHAP. II.

### *Appropriating Commonable Lands*

3476. *Commonable lands*, or such as lie intermixed, or are occupied in common by the inhabitants according to certain laws and customs, may be considered in regard to their origin and kinds, and their appropriation or *dissemin*.

#### SECT. I. *Origin and different Kinds of Commonable Lands*

3477. *A very few centuries ago, nearly the whole of the lands of Britain lay in an open, and more or less in a commonable, state.* (See *Fisherbert on the Statute Extentia Manora*.) Each parish, or township (at least in the more central and northern districts), comprised different descriptions of lands having been subjected during successive ages, to specified modes of occupancy under ancient and strict regulations, which time had converted to law. These parochial arrangements, however, varied somewhat in different districts but, in the more central and greater part of the kingdom, not widely; and the following statement may serve to convey a general idea of the whole of what may be termed common-field townships, throughout England.—

3478. *Each parish, or township, was considered as one common farm*; though the tenantry were numerous. (See also *Blackstone's Commentaries*, art. *Tithing of Townships*.) Round the village in which the tenants resided lay a few small enclosures or grass yards, for rearing calves, and as baiting and nursery grounds for other farm stock. This was the common farmstead, or homestead which was generally placed as near the centre of the more cultivable lands of the parish or township as water and shelter would permit.

3479. *Round the homestead lay a suite of arable fields*, including the deepest and soundest of the lower grounds, situated out of water's way, for raising corn and pulse, as well as to produce fodder and litter for cattle and horses in the winter season and, in the lowest situation, as in the water formed base of a rivered valley or in swampy dips, shooting up among the arable lands, lay an extent of meadow grounds, or *ings*, to afford a supply of hay, for cows and working stock, in the winter and spring months.

3480. *On the outskirts of the arable lands*, where the soil was adapted to the pasturage of cattle or on the springy slope of hills less adapted to cultivation, or in the fenny bases of valleys which were too wet, or gravelly lands thrown up by water which were too dry to produce an annual supply of hay with sufficient certainty one or more stunted pastures, or *hams*, were laid out for milking cows, working cattle, or other stock which required superior pasturage in summer.

3481. *The bleakest, worst-soiled, and most distant lands of the township*, were left in their native wild state, for timber and fuel, and for a common pasture, or suite of pastures, for the more ordinary stock of the township, whether horses, rearing cattle, sheep, or swine, without any other stint or restriction than what the arable and meadow lands indirectly gave every joint tenant or occupier of the township having the nominal privilege of keeping as much live stock on these common pastures, in summer, as the appropriated lands he occupied would maintain in winter.

3482. *The appropriated lands of each township* were laid out with equal good sense and propriety. That each occupier might have his proportionate share of lands of different qualities, and lying in different situations, the arable lands, more particularly, were divided into numerous parcels of *stots*, doubtless, according to the size of the given township, and the number and rank of the occupiers.

3483. *The whole was subjected to the same plan of management*, and conducted as one common farm; for which purpose the arable lands were divided into compartments, or "*fields*," of nearly equal size, and generally three in number, to receive, in constant

rotation, the triennial succession of fallow wheat (or rye), and spring crops (as barley, oats, beans, and peas thus adopting and promoting a system of husbandry which, howsoever improper it has become in these more enlightened days, was well adapted to the state of ignorance and vassalage of feudal times. When each parish or township had its sole proprietor the occupiers being at once his tenants and his soldiers, or meaner vassals, the lands were, of course, liable to be more or less deserted by their occupiers, and left to the feebleness of the young, the aged, and the weaker sex but the whole township being in this manner, thrown into one system, the care and management of the live stock, at least, would be easier and better than they would have been under any other arrangement and, at all times, the manager of the estate was better enabled to detect bad husbandry and enforce that which was more profitable to the tenants and the estate, by having the whole spread under the eye at once, than he would have been had the lands been distributed in detached unenclosed farmlets, besides avoiding the expense of enclosure. Another advantage arose from this more social arrangement, in barbarous times — the tenants, by being concentrated in villages, were not only best situated to defend each other from predatory attacks, but were called out by their lord, with greater readiness, in cases of emergency. Therefore, absurd as the common-field system is, in almost every particular at this day it was admirably suited to the circumstances of the times in which it originated the plan having been conceived in wisdom, and executed with extraordinary accuracy as appears in numberless instances, even at this distance of time.

3484 *Uninhabited tracts or forests.* In different parts of Britain there were and still are, extensive tracts of land, some of them of a valuable quality lying nearly in a state of wild nature, which were never inhabited unless by freebooters, and homebred savages. These uninhabited tracts are styled forests and, heretofore many or most of them have been attached to the crown and some of them are still under royal patronage. Whether they were originally set out for royal pastime merely or whether the timber which stood on them was of peculiar value or whether at the time of laying out townships, those tracts were impenetrable woods inhabited by wild beasts, and, when these had been destroyed or sufficiently overcome to render them objects of diversion, were taken under the protection of the crown is not, perhaps, well ascertained. There were also tracts of that description in different parts of England but which appear evidently to have been enclosed from a state of woodland or common pasture though it is possible they may have been nominally attached to neighbouring parishes. Of this description, principally are the Wealds of Kent and Sussex and many other old enclosed lands, in different parts of the kingdom, whose fields or enclosures are of irregular shapes, and their fences crooked. These woodland districts are like the forest lands, divided into manors, which have not an intimate connection or correspondence with parishes or townships — a further evidence that they were in a wild state when the feudal organisation took place.

3485 *In the western extreme of the island, the common-field system has never perhaps been adopted;* it has certainly never been prevalent, as in the more central parts of England. There, a very different usage would seem to have been early established, and to have continued to the present time, when lords of manors have the privilege of letting off the lands of common pastures to be broken up for corn, the tenant being restricted to two crops, after which the land is thrown open again to pasture and it is at least probable, that the lands of that country have been cleared from wood, and brought into a state of cultivation through similar means. At present, they are judiciously laid out, in farms of different sizes, with square straight-lined enclosures, and with detached farmsteads situated within their areas the villages being generally small and mean — the mere residences of labourers. Circumstances these are, which strongly evince that the common-field system never took place in this part of the island, as it did in the more central parts of England. Ireland, also, has been enclosed (though not fenced) from time immemorial.

3486 *The feudal organisation, having lost its original basis has itself been mouldering away, more particularly during the last century.* A great majority of the appropriated common-field lands and commons have been partially or wholly enclosed either by *possession*, each proprietor enclosing his own slip — a very inconvenient mode of enclosure; or by *general consent* the whole of the proprietors agreeing to commit their lands to the care and judgment of arbiters, or commissioners who, restoring the fields to their original entirety repartitioned them out in a manner more convenient to the several proprietors, and laid each man's portion, which had consisted of numberless narrow slips, in one or more well shaped grounds.

3487 *In England this requires to be effected by a separate act of parliament for each enclosure.* In these acts commissioners are named, or directed to be chosen by the proprietors, who, according to certain instructions in the act or law and the general principles of equity divide the township among all who have an interest in it. It appears by the *statute books*, that from the year 1774 to the year 1812, no fewer than two thousand six hundred and thirty-two acts of enclosure have been passed; the average in the first twenty years being thirty-seven, and in the last twenty years ninety-four.

1685. An *act* defining a general bill of enclosure was passed by the parliament in 1685, and in consequence of it the whole country has for nearly a century past been in distinct possessions. In Ireland, as we have already remarked, no enclosure act became necessary and the country is considered as suffering from the long continued undividedness of landed property.

69th. *As a contrast to the general argument for enclosure, it may be useful to present the moderate, and in our opinion judicious, observations of Loeb, to whom it appears very doubtful how far the indiscriminate enclosure of commons, arising out of the high nominal price of grain has been in every instance of advantage to the nation. Many of them, he says, certainly could never pay the expense of obtaining the act, of the commissioners fees, of the construction of the fences, and of bringing the land into cultivation. In this respect there has been a dead loss of capital to the country. It is conceived that it is not carrying this feeling too far to regret the destruction of some of those beautiful and picturesque forests and chases which once surrounded London, and to hope that this may go no further. It may even be permitted perhaps, to include within this regret as a national loss, the destruction of Windsor forest, the most appropriate accompaniment of the noblest royal residence in Europe. The preservation of some of these chases is as essential to the poorer classes of the metropolis as to the rich. To the former they afford health, exercise, and amusement. In the latter they produce and cherish that love of the country, and of rural sports, so important in a constitutional point of view. They nourish that feeling for and knowledge of the beauties of nature (freed from the love of gain as connected with the productions of the soil) which enlarge our understandings, and excite every better sentiment of the heart — encouraging the practice of the social virtues, and checking these more selfish habits which the general distribution of great wealth is too apt to engender. There cannot be a doubt, that not only for these reasons would the shutting from some of these enclosures have been beneficial but, in an economical point of view it would have been most advantageous to the nation. In how many ways could not the capital, thus lost, have been beneficially applied both for the individual and the country! How much a richer man would the land-owner have been, if he had saved much of this expense, and permitted a more liberal importation of foreign corn! How much better would it have been for the country! In this as in every other instance, it might be demonstrated, that that which would have been best for one, would have been so for all and that the same system must always benefit equally the English landlord, tenant, merchant, manufacturer, and artisan. (Marquess of Stafford's Improvements &c.)*

## SECT. II. General Principles of appropriating and dividing Commonable Lands.

3490. *There are few lands in Britain unappropriated, except in England, and these may be classed as forest lands, and other extensive wastes, on which several manors, or adjacent townships, have a right of common pasturage. Commonable lands of distinct townships or manors, whose appropriated lands are wholly enclosed, and in a state of mixed cultivation. Commonable lands of townships, whose arable fields, &c. are partially enclosed and commonable lands of townships, whose arable fields remain wholly open.*

3491. *The principles on which the appropriation of those lands requires to be conducted are thus laid down by Marshall. By an established principle of the general law or constitution of the country immemorial custom establishes right. Hence the original rights and regulations respecting the lands under view are not now the proper subjects of investigation nor are the changes that may have taken place during a succession of centuries, from the origin of forests and townships to the latest time which is no longer within memory, objects of enquiry, but solely the acquired rights which exist in a given case at the time of appropriation, and which would continue to exist were it not to take place. The possessor of a cottage which has enjoyed from time immemorial and without interruption, the liberty of pasturage, though such cottage were originally an encroachment of a freebooter or an outlaw, has indisputably as legal a claim to a proportionate share of the commonable lands, as the possessor of the demesne lands of the manor has, merely as such, although they may have descended from father to son from the time of their severality for it is evidently on the estimated values of the respective rights which exist and which can be rightfully exercised in time to come, and on these alone that a just and equitable distribution can be effected.*

3492. *But before the distribution of commonable lands among the owners of common pasturage can take place, the more abstract rights which belong to commons require to be estimated, and the just claims of their possessors to be satisfied. These are principally manorial rights, and the rights of tithes.*

3493. *Manorial claims are to be regulated by the particular advantages which the lord of a given manor enjoys, and which he will continue to enjoy while the commons remain open and unappropriated whether they arise from mines, quarries, water timber alien tenants, fuel, estovers, pannage, or game. His claim as guardian of the soil that is productive of pasturage only is, in most cases, merely honorary and it remains with parliament to fix the proportional share of the lands to be appropriated, which he shall be entitled to as an equivalent for such honorary claim.*

3494. *But in the case of throwing timber standing on the property, the claim of the lord of the manor in right of the soil is more substantial for out of this he has in effect a real yearly income, equal to the annually increasing value of the timber; — a species of advantage which, if the commons remain open and unappropriated, he will of course continue to enjoy so long as the timber continues to increase in value. His claim, therefore in this respect, depends on the quantity of timber and its state of growth, taken jointly. Young throwing timber not only affords an annual increase of value at present, but will continue its benefits for many years to come, if it be suffered to remain undisturbed on the soil; and its owner, doubtless, has a prospective claim on the soil which supports it during the estimated period of its future increase; whereas dotards and stunted trees,*

which afford no increase of value, do not entitle their owner to any share of the soil they stand upon. All that the lord has a right to claim appears to be limited to the trees themselves or their intrinsic value.

3495. *The claims of tithe owners, aggregately considered, are more complex and obscure.* In cases where the great and small tithes are united, and in which the tithes of wool and lambs, and that of grain, roots, and herbage, belong to the same owner, it may seem to be reasonable that he should have the option of receiving land of equal value to the existing value of the tithes, or of taking the chance of their value, in the state of cultivation. But seeing the evil tendency of corn tithes, and the impropriety of laying on so harmful a burthen, as they are now become, upon lands that have never borne it, there can be little risk in saying that it would be at least politic in parliament to prevent it. Besides, it stands part of the statute law that lands which have never been under tillage shall not pay tithes during the first seven years of their cultivation during which time the incumbent's income might, by leaving the tithe to take its course, be materially abridged, and his circumstances thereby be rendered distressful. On the whole therefore, it appears to be proper in this case, that the law to be enacted should instruct commissioners to set out lands equal to the existing value of the tithes at the time of appropriation and where much corn land shall be appropriated, to set out a further quantity equal to the estimated reversion of their extra value (if any arise in the estimate), seven years after the appropriation shall have taken place.

3496. *Again, in cases in which the tithes of lambs and wool, and the tithe of corn, &c. belong to separate owners, the line of rectitude and strict justice to all parties appears to be still more difficult to be drawn.* The former is clearly entitled to land, or a money payment equal to his loss of tithe, but the right of the latter is less obvious. To cut him off entirely from any share of the lands, and likewise from any share of tithes to arise from them after they shall have been appropriated, may seem unjust; he may be a lay rector, and may have lately purchased the tithes, or a clerical rector who has recently bought the advowson under the expectation of an enclosure. On the other hand, it appears to be hard, that the proprietors of the parish should first give up land for the tithe of wool and lambs which will no longer exist, and then be liable to a corn tithe on the same lands, after they shall have bestowed on them great expense in clearing and cultivation. In deed, the injustice of such a measure is evident. A middle way therefore, requires to be sought and it will be difficult, perhaps, to find one which has more justice in it than that which is proposed for the first case. Thus, after the value of the lamb and wool tithes, &c. has been ascertained, and land set out as a satisfaction for it, estimate the value of the corn tithe, &c. seven years after the time of appropriation and set out a further quantity for the reversion of the extra value (if any) of the latter over the former and thus free the lands entirely from this obstacle to their improvement.

3497. *If any other abstract claim on the lands to be appropriated be fairly made out, or any alien right (as that of a non-parishioner or extra-manorial occupier, who has acquired, by ancient grant or by prescription the privilege of depasturing them) be fully proved, its value requires to be accurately estimated, and land to be assigned in its stead.*

3498. *The remainder of the untinted commons of a given township or manor belong to the owners of its common-right lands and houses but in what proportion, it may be difficult to determine with mathematical precision.* Nevertheless, by adhering strictly to the general principle, on which alone an equitable appropriation can be conducted — namely that of determining each man's share by the benefit which he has a right to receive at the time of appropriation and which he might continue to receive were it not to take place, — truth and justice may be sufficiently approached.

3499. *One of the first steps toward an equitable distribution of untinted commons is to ascertain the common-right houses, and to distinguish them from those which have no right of commonage and which, therefore, can have no claim to any share of the lands of the untinted commons, further than in the right of the lands they stand upon.* By an ancient and pretty generally received, though somewhat vague, idea respecting the rights of commonage, the occupier of every common right house has the privilege of depasturing as many cattle, sheep, or other live stock, on the common in summer (provided, it must be understood, that it is large enough to permit every occupier to exercise this right), as the grounds he occupies within the township or manor can properly maintain in winter; and no one can exceed that proportion for the surplus of the pasturage, if any, belongs to the lord of the soil. (See *Fisherbert* and *Blackstone*.)

3500. *Under this regulation, the appropriated lands of a common-field township, which are not occupied jointly with a common-right house, may be said to be deprived, during the time they are so occupied, of their right of commonage and in some of the private bills of enclosure, which have been suffered to pass through parliament, the lands which happened to be in this state of occupancy at the time of passing the bills, were deprived*

of their interest in the common lands for ever notwithstanding, perhaps, they had a few years preceding this accidental circumstance an undoubted right to their portion of them, — a right which a few weeks or a few days afterward, might have reverted to them, without the smallest taint by the temporary alienation. If any of the appropriated lands of a township or manor have been estranged from its commons, during time immemorial have never been occupied jointly with a common right house or in any way enjoyed, of right, the common pasturage within memory they may with some reason be said to have lost their right, and be excluded from a participation.

3501. *By the ancient and in a degree essential usage common-right houses have a clear right to the lands of the commons, superior to that of the ground they stand upon especially if they rightfully enjoy a privilege of partaking of the fuel and pannage (as acorns, masts, &c.) they afford, for these properly belong to the houses, not to the lands and still more especially if they are conveniently situated for enjoying the several benefits which the commons afford in their wild state. And whatever a common-right house is worth, merely as such that is to say, whatever it will let or sell for, over and above a noncommon-right house of the same intrinsic value it certainly ought to participate in the distribution, according to such extra value*

3502. *The true proportionate shares of the common-right lands are to be ascertained on the same principle for although the ancient regulation respecting common-rights may continue in force, while the commons remain open and unappropriated, it would be found troublesome or unmanageable as a rule to their just appropriation. There are few if any, commons (of common-field townships at least) that now afford pasturage in summer for all the stock which the appropriated lands are capable of maintaining in winter so that their several proportions only could be used and these proportions may be calculated with much greater certainty and despatch on the respective rental values of the lands, than on the more vague and troublesome estimation of the quantities of stock they would winter which, indeed, would be best calculated by the rental value of the land. Consequently in adopting this as the basis of calculation, the ancient rule is, in effect, complied with (Blackstone book iii c xvi. sect. 2.)*

3503. *But although each common-right occupier has a right to stock in proportion to the productiveness or rental value of his appropriated lands, every one could not do this with equal profit, and of course could not receive equal benefit. Lands situated on the side of a common are much more beneficial in this respect, than lands which lie a mile or two from it, with bad roads between them and it is the real advantage which an occupier can fairly receive, that is the true guide in the partition, which consequently ought to be conducted, not on the rental value of the land, abstractly considered, but on this and its situation with respect to the commonable lands jointly In other words, it is the rental values of the common-right lands while the commons remain open not what they will become after the commons are enclosed, which I conceive to be the proper groundwork of appropriation.*

3504. *In cases where commonable lands are wholly attached to manors, and not common to the parish or township in which they are situated, as in forests and woodland districts, the selfsame principle of distribution is applicable. The remainder of the commons (after the owners of abstract rights have been satisfied) belong to the common-right lands and houses no matter whether such lands and houses belong to copyhold tenants exclusively, or to copyholders and freeholders jointly provided the immemorial custom of the manor make no distinction in their respective rights the well established customs of manors being in all cases rules of conduct, and unerring guides to commissioners. Here may be said to end the greater difficulties as to the principles of appropriation the rest is merely technical the works of admeasurement, estimate, and calculation, — operations that are familiar to professional men in every district, and want nothing but application and integrity to render them sufficiently complete*

3505. *The technical routine of the business of conducting an enclosure is as follows — The act being passed, and two or more commissioners named, these commissioners meet on a certain day at a certain place within the township or parish having previously given public notice of their intention. The chief business of that day is the fixing of a land surveyor and an attorney to the commission. At a second meeting the commissioners, surveyor, attorney, and some of the principal proprietors or their agents, attend and make a general perambulation of the township, in order to point out to the surveyor the different properties, with their limits, &c. The surveyor now proceeds to make a correct map of the whole. This done, the commissioners, attended by the surveyor proceed to value each separate lot or piece; and having done this, they next advertise different meetings for the purposes of hearing the rights of townsmen, &c. Next they set about dividing the lands according to these rights, reserving proper roads for footpaths, quarries, gravel-pits, wells, springs, &c. for public purposes. When this is done, and set out on the ground, contractors are next employed to carry the whole into execution, the expense of which and also of the commission is generally paid by the sale of a part of the lands.*

## CHAP. III.

*Choice of the Demesne or Site for the Proprietor's Residence.*

3506 *The most desirable situation for the mansion of the owner of a landed estate will, in almost every case, be somewhere near its centre.* The advantage of being at an equal distance from every part of the boundaries of having as much as possible on every side that which we can call our own of not being overlooked by near neighbours, and of reposing as it were in the bosom of our own tenantry cottagers, cattle, and woods are obvious, and felt by every one. There may be instances where, from a public road passing through the centre of an estate, or of a town or village there situated, or mining works carried on, and similar circumstances, it may not be desirable to form a central residence, but such cases are not common, and, in laying out an estate newly appropriated, or re-arranging an old one, may always or very generally be avoided. It may happen, however, that an estate may be so extensive or its surface so hilly or mountainous, that a central situation may be dispensed with for other advantages. When an estate is situated near an extensive lake, at the foot of high mountains, or includes an extent of sea-shore, it will generally be found preferable, in point of effect and enjoyment, to place the mansion near these interesting features. Proximity to the sea, though it be on the margin of our estate can never be offensive for if the ocean does not belong to us, neither does it belong to any one else nearly the same thing may be said of an immense lake, which at least is for the greatest part devoid of visible appropriation, and the same thing may often be observed of rivers and mountains, especially if the latter are of a savage, or wooded character.

3507 *Various other circumstances must also be taken into view, in fixing on the situation of a mansion and demesne* such as its healthfulness, prospects, exposure, water the nature of the soil and the extent of territory.

3508 *To be healthy* a situation should in almost all cases be somewhat elevated above the adjoining surface; and though this cannot be the case with respect to the whole of the demesne lands, it should at least apply to the spot intended for the dwelling house. Even a level situation is objectionable in point of health, because, when the usual plantations have grown up round the house, they tend to stagnate the air and generate moisture, and thus deteriorate the atmosphere to their own height, which generally equals or exceeds that of the house. Besides, a flat situation can never have views of much beauty and can only be interesting from the plants or other objects immediately under the eye, and the elevated grounds or hills, if any in the extreme distance. On an elevated situation, even though surrounded by trees higher than the house the frequent and varying winds will always prevent the stagnation of the air, and sweep away the moisture accumulated from the evaporation of so many leaves.

3509 *The nature of the soil* requires to be attended to even with a view to health. On a level, a gravelly or sandy soil is generally more apt to generate damp in the lower parts of a house than a clayey soil but on an eminence gravel has not this objection in the former case, the water lodged in the stratum of gravel finds its way from all sides to the excavation made for the foundations of the house, in the latter the declivity on every side carries it away. Clay not too adhesive chalk, and rock, are the best surfaces to build on in a flat on an elevated situation any soil will do, but chalk rock or gravel, is to be preferred.

3510 *The prospects from the immediate site of the mansion and from those parts of the adjoining grounds which will be laid out as pleasure-ground or recreative walk,* demand some consideration. Such prospects should consist of what painters call middle and third distances, bold distinct, and interesting the fore-ground, or first distance being formed by the artificial scenery of the pleasure-ground. Noble features in prospects are, rivers, lakes, or mountains. In erecting ones are, churches or their spires, bridges, aqueducts, ruins of ancient castles or abbeys, water-mills, distant towns or cities, distant canals, and sometimes roads, &c. pleasing rural objects are, picturesque cottages, neat farmhouses, field barns, and sometimes distant windmills for objects offensive, when near often become valuable features at a distance. *Something depends on the state of civilization of the country and its general character* the sight of a road, sea-port, canal, or even a neighbouring mansion, would be preferred to most others in many parts of Ireland, Russia, or America.

3511 *The exposure with regard to the sun and the prevailing winds of a country,* also requires attention. It was the custom of former times, in the choice of domestic situations, to let comfort and convenience prevail over every other consideration. Thus the ancient baronial castles were built on the summits of hills, in times when defence and security suggested the necessity of placing them there, and difficulty of access was a recommendation but when this necessity no longer existed (as mankind are always apt to fly from one extreme to the other) houses were universally erected in the lowest situ-

ations, with a probable design to avoid those inconveniences to which lofty positions had been subject; hence the frequent sites of many large mansions, and particularly abbeys and monasteries, the residence of persons who were willing to sacrifice the beauty of prospect for the more solid and permanent advantages of habitable convenience amongst which, shelter from wind, and a supply of water for store fishponds, were predominant considerations. (*Enquiry, &c. by Repton, p. 83.*) In hilly countries, or in any country where the surface is varied, the choice is neither made in the bottoms (Ag 532. a) nor on

the summits of hills (c), but generally on knolls, or on the south or south-east side of considerable eminences (b), upon an elevated platform, either natural or raised by art from the earth of the foundations, and the rising grounds behind (d) are planted both for effect and shelter.

5312. The proximity of water is essential to the comfort of every country residence. Where there are none in springs or surface streams, it may, indeed, be collected from the roofs of buildings and otherwise, and filtered, and preserved sweet and cool in tanks underground but supplies obtained in this way are precarious and expensive, and the water is inferior to that obtained from the soil by contiguous wells, or from a distance by pipes or drains. Water is also extensively required in country residences for the use of gardeners, sometimes for fishponds, at a moderate distance, and on a lower level, it is always desirable in considerable quantity for the purpose of forming artificial lakes, or river-like reservoirs. Few home features are finer than where the house is situated on a knoll which slopes down on two or more sides to one encircling piece of water (Ag 533.)

5313. The nature of the soil is a consideration inferior to the others, because all bad soils are susceptible of great improvement, but, still, it should be taken into consideration along with other objects. A soil retentive of surface water such as some clayey and soft peaty soils, is the worst, as it is always unpleasant to walk on after rains, and easily poached by cattle and horses. Such soils also require more expense in drainage and roads, and are much less suitable for garden and farm culture, than firmer soils, and such as are naturally friable or dry.

5314. The subsoil is sometimes of more importance than the soil for the former in general can only be improved by draining, and subsoils differ materially in their susceptibility of this improvement. A bad subsoil is an effectual barrier to the thriving of timber trees; and as these constitute the finest ornament of every country seat, the importance of choosing a subsoil either naturally congenial to them, or capable of being rendered so by art, is sufficiently obvious.

3515. *Where the surface-soil is dry and poor*, but on a dry subsoil, and all other circumstances are favourable, it may often be desirable for a proprietor to fix on such a situation for his demesne; because such a surface is probably among the least valuable as farm lands, because land to be laid out as a park is not required to be rich, and because it will not be difficult to ameliorate all that part wanted as farm and garden ground.

3516. *The extent that should be kept as a demesne* is more easily determined than any of the foregoing points. The general wealth of the proprietor, and his style of living are here the leading guides. The extent of the demesne may bear very different relations to the extent of the estate because the proprietor may have other estates and other sources of wealth. He may have chosen a small estate, on which to fix his residence, from its local advantages or he may prefer a small demesne on a large estate, from his style of life and the habits of his establishment.

3517. *The park* in general, occupies much the largest part of the demesne lands. In a civilised and populous closely cultivated country like Britain, nothing can be more noble than a large forest-like park surrounding the mansion. In partially cultivated countries, or open field countries, it is less imposing and in countries scarcely appropriated and but thinly distributed with spots of culture, the park becomes a less noble feature, and less a mark of wealth and distinction than a well-bedged and regularly cropped farm.

3518. *The apparent extent of a park* depends much less on its contents in acres, than on the inequalities of its surface, the disposition of its woods and waters, and the concealment or unobtrusiveness of its boundaries. An extensive flat, surrounded by a belt, and interspersed with clumps, may be great, but can hardly be felt as grand or interesting by any but the owner the acres it occupies will be guessed at by hundreds, and the estimate will generally be found to fall short of the reality. On the other hand, a hilly park, ingeniously wooded, with a piece or pieces of water and probably rocks, bridges, and other objects, will appear to a stranger of much greater extent than it really is, and sets rational estimate at defiance such a park is certainly much more grand and picturesque than one of mere "bulk without spirit vast."

3519. *The home or demesne farm and farmery* will be regulated in extent and style of cultivation by the wants and wishes of the proprietor. It is sometimes a determinate space in the least picturesque part of the demesne and sometimes, the greater part of the park is brought in succession under the plough and the sickle.

3520. *The kitchen-garden* is the next and only remaining large feature in the demesne it is generally placed near the house and stable offices, so as to have a convenient and unobtrusive communication with the kitchen court, and the livery-stable dung heap.

3521. *The pleasure-ground, or lawn and shrubbery* often surrounds the house, offices, and kitchen-garden and sometimes embraces them only on two or three sides.

3522. *The details* of all these and other parts of the demesne belong to landscape-gardening and architecture and require no further notice in this work. (See *Encyc. of Gard.* part iii. book iv.)

#### CHAP. IV

##### *Formation and Management of Roads.*

3523. *The advantages of good roads* are so obvious and so generally acknowledged, as to need no comment. Roads, canals, and navigable rivers, have been justly called the veins and arteries of a country, through which all improvements flow. The Romans, aware of their importance, both in a military and civil point of view constructed them from Rome to the utmost extent of their empire. With the dismemberment of that empire, the roads became neglected, and continued so during the dark ages. In modern times attention was first paid to them on a large scale by the government of France, in the seventeenth century, and in England in the beginning of the century following. About the middle of the eighteenth century, considerable expense had been incurred in road-making in several districts, and the expenses of toll gates began to be felt as oppressive. This produced *An Enquiry into the State of the Public Roads*, by the Rev. H. Homer, &c. 1767 which may be considered as the origin of scientific research on the art of road-making in England.

3524. *In Scotland*, the first turnpike act, as we have seen (771), was passed in 1750; since which period existing public roads have been improved, and many new ones formed; but the great impulse there was given, after the act for abolishing heritable jurisdictions, by the money advanced by government, and the able military engineers sent from England to conduct the roads in the Highlands. The appearance in Britain, about this time, of a new order of professional men, under the name of civil engineers, also contributed to the same effect.

3535. In Ireland, very little attention was paid to the art of road-making before the establishment of the Dublin Society; but the subject was treated of in the early volumes of their *Transactions*, and some useful instructions there given, as it is generally understood, by R. L. Edgeworth and the surface as well as substrata of that country being singularly favourable for road-making, the art soon began to make considerable progress. This was greatly owing to the exertions of Edgeworth, well known as a scientific engineer and as the author of a tract on roads published in 1810.

3536. The extraordinary increase of toll duties in England, having been felt as a very heavy burthen by the landed interest during the last twenty years, has drawn the attention of various persons to the subject of roads, and given rise to important improvements, both in laying them out, and in forming and repairing them. By far the most useful of these may be considered the mode of forming practised since 1816, by L. M. Adam of Bristol for which its author was rewarded by parliament. That mode is now with more or less variation, adopted in a considerable number of districts in the three kingdoms, and, together with the attention and emulation it excites, promises to effect an entire revolution in the state of the public roads every where. At the same time it is but candid to state, with Paterson of Montrose, author of two tracts (1819 and 1832) on the subject, that in many districts a considerable improvement had taken place, previously to the time of M'Adam, in the state of the roads simply from a greater attention being made to keep them dry by under-drainage, to break the stones small, and constantly to obliterate the ruts.

3537. But M'Adam's plan of making roads promises to be valuable as a substitute for pavement or causeways in towns at the same time its value, as compared with the most improved methods of paving cannot be considered as finally determined.

3538. In the following view of the present state of knowledge as to roads we shall avoid entirely that part of the subject which relates to national or parochial management, and confine ourselves to the kinds, the direction or line, the form, the materials, the execution, and the repairs.

#### SECT. I. Different Kinds of Roads.

3539. Though all roads agree in being tracks of passage from one point to another yet they differ in their magnitude, construction, and other modes of adaptation for that purpose. Most good roads consist of two parts one "metalled" or coated with stones for

the use of carriages and horses (fig 534 a) another of common earth or soil as a border to the metalled part (b) or for the use of

pedestrians and probably a footpath for the latter (c). Several kinds of roads are distinguished by the relative proportions of these two parts but some also are characterised by other circumstances.

3540. *National roads*, or highways, are such as communicate between the capital cities and sea-ports of a country and are those of the greatest magnitude. In Britain, the metalled part of such roads, where they are most frequented, as within a few miles of large towns, is from 30 to 50 and even to 60 feet wide with footways on each side of 12 feet wide or upwards, and in no case is the metalled part of the road narrower than 20 feet that width being requisite to admit of one loaded waggon passing another. Many or most of these narrower national roads are without footpaths, and often want a sufficient bordering of earth road, or footpath.

3541. *Parochial roads* may be considered as secondary highways, deriving their name from the circumstance of being made and supported by the parish in which they are situated whereas the others are the work of government, or of the counties in which they are situated, and are supported by tolls levied on carriages and animals passing over them.

3542. *Lanes* are parish or private roads, generally narrow and often either not metalled at all, or very imperfectly so sometimes they are called *drift-ways*, but that term is more properly applied to the green or unmetalled space which runs parallel to any made road, for the passage of flocks and herds.

3543. *Estates roads* are such as are made by landed proprietors on their own territory, for the purpose of intercommunication and connection with public roads.

3544. A *farm-road* is either one which leads to a farm from a public road, or which leads from the farm to different parts of the farm. Such roads are never narrower than 16 feet, to admit of two carriages passing each other but they are often only half metalled, presenting a turf road for summer, dry weather and for empty carriages and foot passengers, and a metalled or winter road for winter and loaded carriages. In a road from a highway to a farm, it may often be advisable to place the metalled road in the middle, and keep the earth road at each side on account of admitting the sun and air more readily to the metalled road but in roads within a farm, it is found a great convenience in carting out manure or bringing home produce, for the loaded carts to have

uninterrupted possession of the metalled road, and the others of the earth road. In many cases, farm roads of this description are only metalled in the horse tracks

(fig 535 a) and wheel ruts (b c), which, on dry firm-bottomed land, and with careful preservation, is found to answer very well.

5355. *Open farm roads*, Beaton observes, should be, as much as possible, placed

on the headlands of the fields that is, the portion of land adjacent to the hedges, on which the plough is turned and every opportunity should be taken of placing gates, so that either

side of a hedge may be used as a road (fig 536.), to avoid driving over a field in tillage. This may be easily effected by a few gates being placed in the line of the headland or nearly so, and not too near each hedge or to each other so that a waggon may easily drive through them on the right or left, as the crops may require a few hurdles (a) may guard each field in grain alternately and will furnish a useful fold or enclosure to detain sheep colts, &c.

5356 *Horse roads* are paths for the transit of single horses with a rider, or a back load they are commonly of earth, and from six to ten feet wide the statute width is eight feet.

5357 *Footpaths* are tracks for pedestrians sometimes metalled to the width of three or four feet but often of the natural surface.

5358 *Paved roads* are of three kinds those with small stones, or causeways, which are most common those with large blocks of stone, or what is called ashlar pavement and those with sections of timber

trees. The first though almost peculiar to towns, yet form the whole of the metalled road in some cases of country roads and in others a space of ten or twelve feet in the middle, or at each side, is causewayed for the use of the heavier carriages. Broad stones are sometimes used for covering part of a road, destined for the greatest part of the traffic or for forming wheel tracks. In the latter case they are always squared or regularly jointed, but in the former the most irregular forms may be used. Timber causewaying is only used in entrance courts to town mansions, for the sake of avoiding the noise made by the wheels of carriages and horses feet on stone or on suspension bridges, for the sake of lightness. For these purposes timber paving is excellent, and lasts for a very long time. On the Continent, fir timber is used for this sort of paving; but oak or larch would, no doubt, last longer

5359. *Street roads with stone tracks* (fig 537) have been proposed by Mr Stevenson, a distinguished engineer These tracks may either be laid in connection with common

or rubble causeway (a), or with common road metal (b) Mr Stevenson proposes to lay these stone tracks upon a firm foundation, if not throughout the whole extent to

our principal roads, at least upon all their acclivities which exceed a greater rise than at the rate of 1 perpendicular to 26 horizontal feet — an undulating line of road which obliges the carrier in most instances, to modify his load to one half of what his horse can take along the more level parts. It is likewise proposed, that the leading streets of all towns and villages situate upon the principal highways should be paved with these stone tracks. The traveller would then glide smoothly along, instead of being accompanied with a thundering noise and jolting motion most unpleasant to himself and the inhabitants of the respective places through which he passes.

3540. *The advantages of stone tracks in roads* " cannot be better exemplified than by noticing an experiment made in presence of some of the Directors of the Forth and Clyde Canal Company upon a set of cast-iron tracks, laid upon an acclivity rising at the rate of about 1 in 15 to Fort Dundas, near Glasgow. Here one horse actually drew up a load of three tons on a cart weighing nine cwt. In this case the horse proceeded up hill without much apparent difficulty till he reached the top, and was about to enter on the common causeway when he could proceed no further although the road had now become level. The carriers frequenting this road agree that their horses had formerly greater difficulty in taking up twenty four cwt. on the causeway than was now experienced with three tons. How great, therefore, must be the beneficial effects of such an immense accumulation of power as even the partial introduction of wheel-tracks is calculated to afford to the traffic of the country!"

3541. *Mr Stuart Montagu of Cloosburn* " has had single-horse waggons with four wheels applied to the ordinary purposes of his estate. These waggons are constructed upon the principle of those of Switzerland they are ten cwt on which a horse weighing about eleven cwt. takes a load of thirty cwt. between Edinburgh and Cloosburn a distance of sixty-six miles. This gentleman whose knowledge in such matters is extensive, estimates, that if wheel-tracks were laid upon the principal acclivities of the road, as above recommended, his horses could work with a load of about two tons." (*Swissman's Plan for Track Roads*, Edin. 4to. 1825, p. 4.)

3542. *Planked roads* are formed over morasses or in particular cases by laying down a flooring of planks on which carriages pass for temporary purposes. A permanent kind of road of this description has been made by weaving (or wattling) an endless hurdle of the breadth of the road, and covering it with a coating of gravel or broken stones. The advantage of this mode is, that the road may be made on a bog before the substratum dries, and even if it is so soft as not to bear a man. By the time the hurdle rots, the base will be consolidated and fit to bear any thing.

3543. *Rail roads* are roads exclusively for the use of carriages, and are characterised by a rail, commonly of iron, but sometimes of wood or stone laid along the track of each wheel in order to produce the effect of a perfectly even surface. There is also a recent invention of this kind, named a suspension railway, which, under particular circumstances, promises very considerable advantages. In general the carriages for such roads have their wheels low, and of a particular construction to fit the rails, but in some cases the rails have grooves for the use of common narrow wheels. Such roads are almost exclusively in use at coal and other great mineral works but it has lately been proposed to introduce them as side roads to the more public highways, for the purpose of locomotive steam-engines, and it seems highly probable that this may be done before long on several of our main roads (See Sect. V.)

#### SECT. II. *Line of Direction, or laying out of Roads.*

3544. *Before carriages of burthen were in use* little more was required than a path upon hard ground, that would bear horses. All marshy grounds were therefore shunned the fords of rivers were resorted to, and the inequality or circuit of the road was of much less consequence, that when carriages, instead of pack horses, began to be employed. When carriages were first employed, they probably were light and narrow and did not require to have roads of any considerable breadth or firmness and when roads had once been thus traced, indolence and habit prevented any great exertions to lay them out in better lines, or to repair them in any manner beyond what present convenience absolutely required. When heavier carriages and greater traffic made wider and stronger roads necessary, the ancient track was pursued. Ignorance and want of concert in the proprietors of the ground, and, above all, the want of some general effective superintending power, continued this wretched practice. (*Edgeworth on Roads*, p. 3.) At length turnpikes were established, and laws passed investing magistrates with authority to alter established lines, so that now the chief obstacle to the improvement of the lines of public roads is the expense.

3545. *In laying out roads*, a variety of circumstances require to be taken into consideration but the principal are evidently their line or direction, and its inclination to the horizon.

3546. *The most perfect line*, according to Marshal, is that which is straight and level. But this is to be drawn in a country only which is perfectly flat, and where no obstructions lie in the way — joint circumstances that rarely happen. Where the face of the country between two points or places to be connected by a road, is nearly but not quite level, by reason of gentle swells which rise between them, a straight line may be perfect, — may be the most eligible under these circumstances, but where the intervening country is broken into hill and dale, or if one ridge or only intervenes, a straight line of carriage road is seldom compatible with perfection. In this case, which is nearly general, the best skill of the surveyor lies in tracing the midway between the

straight and the level line. The line of perfection, for agricultural purposes, is to be calculated by the time and exertion, jointly considered, which are required to convey a given burthen, with a given power of draught, from station to station. On great public roads, where expedition is a principal object, time alone may be taken as a good criterion.

3547 According to Stevenson, "although in road-making the line of direction must always be subordinate to the line of draught, yet the former is notwithstanding of importance, both as it regards the safety of the traveller, and the trackage of the load. Independently of the numerous accidents which occur from the sudden collision of carriages traveling at speed upon a tortuous line of road, it were even better to go up a moderate acclivity, than to introduce numerous turns, which, to a certain extent, are not less detrimental to the effective power of the horse, than the uphill draught. Every turn in the road, which ultimately amounts to a right angle, does, in effect, suppose the carriage to have been brought from a state of motion to a state of rest, and from rest to motion again. Turns in a road, where they are unavoidable, ought to be formed on curves of as large a radius as the situation will admit. There ought, in laying out a road, to be a kind of compensating balance between the lines of direction and draught and wherever weighty reasons occur for varying the direct line, such as an acclivity to be avoided, more proper soil to be obtained, the avoiding of valuable property or the including of a village or town, — where such motives present themselves, the judgment of the engineer will, of course, be exercised in varying the line of direction (Ed. Enc art. Roads)

3548 A regular method of finding out the true line of road between two stations, where a blank is given, and where there is no other obstruction than what the surface of the ground to be got over presents, is to ascertain, and mark at proper distances, the straight line, which is the only certain guide to the surveyor. If the straight line be found to be ineligible, each mark becomes a rallying point in searching on either side of it for a better. If two lines of equal facility and nearly of equal distance from the straight line, present themselves, accurate measurements are to determine the choice. If one of the best two lines which the intervening country affords is found to be easier, the other shorter, the ascent and the distance are to be jointly considered the exertion and the time required are to be duly weighed.

3549 The nature of the ground, the source of materials, and the comparative expense of forming the road, by two doubtful lines, as well as their comparative exposure, are also to be taken into consideration. Although in some places, Paterson observes, it may be of little consequence, either to the traveller or to the public in general, which way the bendings are turned, provided the level is nearly obtained, yet a great deal may depend upon those turns or bendings for the real benefit and advantage of the road. In bending it one way, you may have no metals that will stand any fatigue, unless at a great distance and expense while, in turning it the other way, you may have metals of the very best quality in the immediate vicinity. In the one way too, you may be led over ground of a wet bottom, where, even with twelve or fourteen inches deep of metals, there would be difficulty in keeping a good road while, in the other you may have such a dry bottom, that the road would be much easier upheld with seven or eight inches of metals. So that the track that may appear most eligible to the eye, at first sight, may not always be the one that should be adopted. "A combination of all the regulatives I have already mentioned should be studied, as far as possible and where these cannot be found all to unite, the one possessing the most of these advantages, and subject to no other material objection, should, of course, be adopted. (Treatise on Roads, p 19)

3550. Roads, Edgeworth observes, should be laid out as nearly as may be in a straight line; but, to follow with this view the mathematical axiom, that a straight line is the shortest that can be drawn between two points, will not succeed in making the most commodious roads hills must be avoided, towns must be resorted to, and the sudden bends of rivers must be shunned. All these circumstances must be attended to therefore a perfectly straight road cannot often be found of any great length. It may, perhaps, appear surprising, that there is but little difference in the length between a road that has a gentle bend, and one that is in a perfectly straight line. A road ten miles long, and perfectly straight, can scarcely be found any where but if such a road could be found, and if it were curved, so as to prevent the eye from seeing further than a quarter of a mile of it, in any one place, the whole road would not be lengthened more than one hundred and fifty yards. It is not proposed to make serpentine roads merely for the entertainment of travellers, but it is intended to point out, that a strict adherence to a straight line is of much less consequence than is usually supposed and that it will be frequently advantageous to deviate from the direct line, to avoid inequalities of ground. It is obvious, that, where the arc described by a road going over a hill, is greater than that which is described by going round it, the circuit is preferable but it is not known to every overseer, that within certain limits it will be less laborious to go round the hill,

though the circuit should be much greater than that which would be made in crossing the hill. Where a hill has an ascent of no more than one foot in thirty, the thirtieth part of the whole weight of the carriage, of the load, and of the horses, must be lifted up, whilst they advance thirty feet. In doing this, one thirtieth part of the whole load continually resists the horses draught and in drawing a waggon of six tons weight, a resistance equal to the usual force of two horses must be exerted.

3551 *A perfectly level road is not always the best for every species of draught.* Slight and short alternations of rising and falling ground are serviceable to horses moving swiftly the horses have time to rest their lungs, and different muscles and of this experienced drivers know well how to take advantage. Marshal concurs in this opinion, and also Walker, Telford, and most engineers and Paterson considers that it would not be proper to line a road upon a perfect level, even to the length of one mile together although it could be quite easily obtained. It is a fact, he says, well known to most people, at least every driver of loaded carriages knows by experience that where a horse, dragging a load over a long stretch of road, quite level, will be exhausted with fatigue, the same length of a road, having here a gentle acclivity and there a declivity will not fatigue the animal so much. This is easily accounted for. On a road quite level, the draught is always the same, without any relaxation but on a gentle ascent, one of his powers is called into exercise on the descent, another of his powers is called into action, and he rests from the exercise of the former. Thus are his different muscular powers moderately exercised, one after another and this variety has not the same tendency to fatigue. A perfectly level road, both with respect to its direction and its breadth, is always dirty in wet weather because the run water can neither run off to the side of the road, nor along the ruts. Such roads, therefore as are level in their line of direction, should always have a fall from the middle to the sides, and should be kept as much as possible free from ruts.

3552 *According to Stevenson,* and we believe to all the most scientific road engineers, a level straight road is decidedly the best. He says, "In an uphill draught, a carriage may be conceived as in the state of being continually lifted by increments proportional to its rise or progress upon the road. Every one knows that on a stage of twelve miles the post-boy generally senses as it is termed, at least half an hour upon the level road, because on it he never requires to slacken his pace as in going uphill. Now if he, or his company would agree to take the same time to the level road that they are obliged to do upon the undulating one, the post-master would find no difficulty in determining which side of the argument was in favour of his cattle. With regard to the fatigue or ease of the horse, Mr Stevenson upon one occasion submitted the subject to the consideration of a medical friend (Dr John Barclay of Edinburgh, no less eminent for his knowledge, than successful as a teacher of the science of comparative anatomy; when the Doctor made the following answer — My acquaintance with the muscles by no means enables me to explain how a horse should be more fatigued by travelling on a road uniformly level than by travelling over a like space upon one that crosses heights and hollows but it is demonstrably a false idea, that muscles can alternately rest and come into motion in cases of this kind. The daily practice of ascending heights, it has been said, gives the animal wind, and enlarges his chest. It may also, with equal truth be affirmed that many horses lose their wind under this sort of training and irrecoverably suffer from imprudent attempts to reduce such a habit. In short, the Doctor ascribes much to prejudice originating with the man, continually in quest of variety rather than the horse, who, consulting only his own ease seems quite unconscious of Hogarth's Line of Beauty." (*Report on the Edinburgh Railway*)

3553 *A dry foundation, and clearing the road from water* are two important objects which, according to Walker (*Minutes of Evidence before a Committee of the House of Commons, 1819.*) ought to be kept in view in lining out roads. "For obtaining the first of these objects, it is essential that the line for the road be taken so that the foundation can be kept dry either by avoiding low ground by raising the surface of the road above the level of the ground on each side of it, or by drawing off the water by means of side drains. The other object, viz. that of clearing the road of water, is best secured by selecting a course for the road which is not horizontally level, so that the surface of the road may in its longitudinal section, form in some degree an inclined plane and when this cannot be obtained, owing to the extreme flatness of the country, an artificial inclination may generally be made. When a road is so formed, every wheel-track that is made, being in the line of the inclination becomes a channel for carrying off the water much more effectually than can be done by a curvature in the cross section or rise in the middle of the road, without the danger or other disadvantages which necessarily attend the rounding of a road much in the middle. I consider a fall of about one inch and a half in ten feet to be a minimum in this case if it is attainable without a great deal of extra expense.

3554 *The ascent of hills,* it is observed by Marshal, is the most difficult part of laying out roads. According to theory, he says, an inclined plane of easy ascent is hypier but as the moving power on this plane is rather purely mechanical, nor in a sufficient degree rational, but an irregular compound of these two qualities, the nature and habits of this power "require a varied inclined plane, or one not a uniform descent, but with levels or other proper places for rests. According to the road act, the ascent or descent should not exceed the rate or proportion of one foot in height to thirty five feet of the length thereof, if the same be practicable, without causing a great increase of distance.

3552. *As proceedings for roads through hilly countries* Telford (*Minutes before the Committee of the House of Commons, &c. 1812.*), refers to those which he has lately made through the most difficult and precipitous districts of North Wales. "The longitudinal inclinations are in general less than one in thirty; in one instance for a considerable distance there was no avoiding one in twenty-two, and in another for about two hundred yards, one in seventeen; but in these two cases, the surface of the road-way being made peculiarly smooth and hard, no inconvenience is experienced by wheeled carriages. On flat ground the breadth of the road-way is thirty-two feet where there is no cutting not exceeding three feet, the breadth is twenty-eight, and along any steep ground and precipices it is twenty-two all clear within the fences the sides are protected by stone walls, breast and retaining walls and parapets great pains have been bestowed on the cross drains, also the draining of the ground, and likewise in constructing firm and substantial foundations for the metalled part of the roadway."

3553. *The road between Chapel Cery and Lord Penrhyn's slate quarries* may also be adduced as an example of a very perfect enclosed plane in which the ascent is accurately divided on the whole space.

3554. *Cutting through low hills to obtain a level* is recommended by some, who, as Paterson observes, will argue, "that where the hill of ascent is not very long, it is better in that case, to cut through it in a straight line and embank over the hollow ground on each side, than to wind along the foot of it. This, however, should only be done where the cutting is very little indeed, and an embankment absolutely necessary. Few people, except those who are well acquainted with the subject, are aware of the great expense of cutting and embanking and the more any one becomes acquainted with road-making, the more, it may be presumed, will he endeavour to a old those levels on the straight line that are obtained only by cutting and embanking and will either follow the level on the curved line round the hill, or where this is impracticable, will ascend the hill, and go over it by various windings, avoiding always abrupt or sudden turnings." (*Treatise &c. p. 16.*)

3555. *All crossings, intersections and abuttings of roads*, should be made at right angles, for the obvious purpose of facilitating the turning from one road to the other or the more speedily crossing. Where roads cross each other obliquely, or where one road abuts on another at an acute angle, turning in or crossing can only be conveniently performed in one direction.

3556. *In laying out a road over a hill or mountain of angular figure and considerable height*, much practical skill, as well as science is requisite. In order to preserve a moderate inclination or such a one as will admit of the descent of carriages without locking their wheels, a much longer line will be required than the arc of the mountain. In reaching the summit or highest part to be passed over the line must be extended by winding or zig-zagging it along the sides, so as never to exceed the maximum degree of steepness. This may occasion a very awkward appearance in a ground plan but it is unavoidable in immense works. If a hill, 50 feet in perpendicular height (fig. 538),

538

has an arc (*a, b, c*) or would require 150 feet of road (*a, b, c*) to go over its summit in a straight line then to pass over the same hill on a road rising at the rate of two inches in six feet (the slope of the Simplon road) would require a length of 600 feet. If this length were extended in a straight line (*d, b, e*) on each side it would require an enormous mound, and an immense expense; but by being conducted in a winding direction (*b*) up the hill on one side and down the other the same end is gained at a moderate cost. Such works show the wonderful power and ingenuity of man and perhaps no example exists where this power is so strikingly displayed in road-making as in the case of the Simplon.

3560. *In laying out a road towards a river stream, ravine or any place requiring a bridge or embankment*, an obvious advantage results from approaching them at right angles and the same will apply in regard to any part requiring tunnelling or crossing by an aqueduct, &c.

3561. *In tracing out winding railroads, or such carriage roads as are only to be metalled in the horse track and paths of the wheels*, some management is necessary in the case of quick bends. Where the line is straight, the horse path ought to be exactly in the middle between the wheel tracks but, where the road winds, and most especially at a quick bend, the horse track ought ever to incline toward the outer side of the curve, by which the wheels will be uniformly kept on the middles of the supports prepared for them. Hence, it is advisable to dig the trench for the horse path (fig. 535 *a*) first and to draw a carriage for which the road is intended with the horses walking in this middle trench thus marking out, by the impressions of the wheels, the precise middle lines of the outer trenches, in every part of the road from end to end.

3562. *The directions of roads through an extensive estate* cannot be determined on without having in contemplation the other fundamental improvements, such as the situations of villages, farmhouses, mills, or other objects; and these artificial improvements must be taken in connection with the natural surface, soil materials, waters, &c., the probable system of agriculture that will be pursued, and the external intercourse. A hilly country under aration, will evidently require more roads than if chiefly under

pasture; and, indeed, other circumstances the same, a country abounding in hills and valleys requires many more roads than one of a more even surface. The roads in such a country are also more expensive, on account of the bridges, and extra work at their abutments. On an estate composed of gentle hills chiefly intended for arable or convertible husbandry, the best situation for the roads will generally be found about half way between the bottoms and highest surfaces. By this means the labour of carting up the produce from the fields below the road, and carting up the dung to the fields above it, is evidently much less than if the road were either entirely on the highest ground or the lowest. Bridges over the brooks or open ditches necessary for drainage in valleys, are also rendered less frequent.

3563. *Accurate sections of the rises and falls of the natural surface on which a road is to be formed should always be taken before the line is finally determined on.* As the figure of an exact section of this sort, on any ordinary scale, would convey no data sufficiently accurate for execution, it is usual to adopt one scale for the length, and another for the rises and falls of the road, and to mark the latter with the dimensions as taken on the survey.

### SECT. III. *Form and Materials of Roads.*

3564. *On the structure and composition of roads, men of science and practical road makers are much more divided than on their laying out.* The subject is of itself of greater importance in old countries, because it more frequently occurs that a road is to be enlarged or renewed, than that a new line is to be devised. We shall first lay down the fundamental principles of the formation, and wear of roads and next treat of forming them, and of the different kinds of road materials.

#### SUBSECT. I. *Formation of Roads, and of their Wear or Injury*

3565. *A road may be defined a path of transit on the earth's surface, for men, animals, and machines of sufficient width for the given traffic of sufficient strength and solidity for the given weight of sufficient smoothness to offer no impediment and of as great durability as possible.*

3566. *The width is obviously determinable by the nature and extent of the traffic every road should be made sufficiently broad to admit two of the largest used carriages which are in use in the country or district to pass each other, and highways, and roads near towns, should be made wider in proportion to their use.* The maximum and minimum can only be determined by experience sixty feet is the common and legal width of a turnpike-road in Britain, and this includes the footpath.

3567. *The strength of a road depends on the nature of the material of which it is formed, and of the base on which it is placed.* A plate of iron or stone of the road's width placed on a compact dry soil would comprise every thing in point of strength, but as it is impracticable to employ plates of iron or stone of such a size to any extent, recourse is had to a stratum of small stones or gravel. The great art, therefore, is so to prepare this stratum, and place it on the base of the road, as that the effect may come as near as possible to a solid plate of material. To accomplish this, the stones or gravel should be broken into small angular fragments, and after being laid down of such a thickness as experience has determined to be of sufficient strength and durability, the whole should be so powerfully compressed by a roller as to render it one compact body capable of resisting the impression of the feet of animals and the wheels of carriages in a great degree, and impermeable by surface water. But the base of the road may not always be firm and compact; in this case it is to be rendered so by drainage artificial pressure, and perhaps in some cases by other means.

3568. *In cases of a wet or soft foundation, where from the nature of the soil and the pressure of the springs lying on a higher level, as on the great north road, near Highgate draining has been found inefficient in drying the foundation of the road; the same object has been attained by laying down and joining by cement, blocks composed of coarse gravel and Roman cement.* The water is thus prevented from coming up, and a foundation formed, at once firm, durable, and dry. This invention, with many others in modern road-making belongs to Mr Telford. (*Newton's Journal*, vol ii. p. 23.)

3569. *The durability of a road, as far as it depends on the original formation, will be in proportion to the solidity of its base, the hardness of the material of which the surface-stratum is formed, its thickness, and the size and form of the stones which compose it.* The form and size of the stones which compose the surface-stratum have a powerful influence on a road's durability. If their form is roundish, it is evident they will not bind into a compact stratum if they are large, whether the form be round or angular the stratum cannot be solid and if they are of mixed sizes and shapes, though a very strong and solid stratum may be formed at first, yet the wheels of carriages and the feet of animals operating with unequal effect on the small and large stones would soon derange the solidity of the stratum to a certain depth, and, consequently, by admitting rain and frost to penetrate into it, accelerate its decay. A constant state of moisture, even without any derangement of surface, contributes to the wearing of roads by friction: hence

one requisite to durability is a free exposure to the sun and air by keeping low the side fences; and another is keeping a road clear of mud and dust — the first of which acts as a sponge in retaining water, and the second increases the draught of animals, and of course their action on the road. Both the strength and the durability of a road will be greater when the plate or surface-stratum of metals is flat or nearly so, than when it is rounded on the upper surface first, because no animal can stand upright on such a road with a regular bearing on the soles of its feet, and, secondly, because no wheeled carriage can have a regular bearing, except on the middle or crown of the road. The consequence of both these states is the breaking of the surface of the plate into holes from the edges of horses' feet, or ruts from the plough-like effect of wheels on the lower side of the road, or the reiterated operation of those which pass along the centre.

3570. *The smoothness of a road depends on the size of the stones, and on their compression either by original rolling or the continued pressure of wheels. The continued smoothness of a road during its wear depends on small stones being used in every part of the stratum for if the lower part of it, as is generally the case in the old style of forming roads, consists of larger stones, as soon as it is penetrated by wheels or water from above, these stones will work up and produce a road full of holes and covered with loose stones.*

3571. *The wear or decay of roads takes place in consequence of the friction, leverage, pressure, grinding, and incision of animals and machines, and the various effects of water and the weather.*

3572. *Friction will in time wear down the most durable and smooth material. Its effects are more rapid when aided by water which insinuates itself among the particles of the surfaces of earthy bodies, and, being then compressed by the weight of feet or wheels, ruptures or wears them. Even when not compressed by wheels or other weights, the action of frost, by expanding water produces the same effect. This any one may prove, by soaking a soft brick in water and exposing it to a severe frost. A road in a state of perfect dryness is, under the action of wheels, as liable to be injured in its solidity, as when too wet; because it loses its elastic tenacity under the pressure and becomes broken into a loose superstratum. This is the greatest advantage of watering roads, as proved by the experience of truncheons, and shown in their annual accounts of expenses besides the comfort to travellers, of laying the dust, for which alone watering was first thought necessary.*

3573. *The leverage of the feet of animals has a tendency to depress one part of the surface and raise up another. The line which forms the sole of every animal's foot may be considered as a lever of the second kind, in which the fulcrum is at the one extremity (fig 539 a) the power at the other (b) and the weight between them (c). Hence the injury done to the road even if formed on the best construction, will be as the pressure on the fulcrum this amounts to from the half to the whole of the weight of bipeds and their loads,*

*and from a fourth to a half of that of quadrupeds. But if the stones of the road are large, that is, if they are more than two inches in breadth, the horse's foot acts as a compound lever, and, by depressing one end of the stones and raising the other, deranges the surface of the stratum, and renders it a receptacle for water, mud, or dust.*

3574. *The leverage of wheels is of a nature to be less injurious to roads than that of the feet of animals, because the fulcrum (fig 540. a), is continually changing its position but if the stones of the road are large, then the wheel acts as a compound lever raising up the one end (b) and depressing the other (a'), of every stone it passes over and in this case becomes more injurious on a bad road than the feet of loaded animals. The reiterated operation of this effect, by wheels following in the same track, soon destroys badly constructed roads.*

3575. *Such being the effect of leverage and especially of compound leverage, on wearing roads, it becomes of the first importance to ascertain that size and shape of stone on which its effects will be least; that is to say how short a compound lever may be made use of consistently with other advantages. This must in general be a matter of experience, and chiefly depends on the hardness of the stone. The stone must always be sufficiently large, and the shape sufficiently angular, to form, when embedded, a compact, hard, and*

immovable stratum, and the smaller the size the better, provided that object be obtained. One inch in diameter may be considered the medium size.

3576. *The mere pressure of bodies on a smooth road does little mischief, and hence the advantage of perfectly cylindrical wheels, and a road as nearly level as practicable. But if the surface of the road is rough, the pressure both of cylindrical wheels and the feet of animals may do mischief, by forcing down a loose stone among others of different sizes, and thus loosening the latter and raising the largest to the surface. Where a road, however, is composed of materials of small size, and the surface is clean and dry the advantage derived from the pressure of cylindrical wheels acting as rollers will, it is probable, always be greater than the injury sustained from their friction.*

3577. *Grinding is produced by the twisting motion of the feet of horses or other animals when pulling hard or carrying a heavy weight, and by the twisting, dragging, or sliding of wheels from whatever cause. The grinding of wheels, Fry observes "may in every case be defined to be the effect produced on any substance interposed between two bodies, one of which has a sliding motion, yet so firmly confined or pressed between them, that the moving body cannot slide over the interposed substance but, in consequence of the pressure, the interposed substance, adhering firmly both to the fixed and to the moving body, is necessarily lacerated or torn asunder and reduced to atoms. Thus is the process in corn-mills, in drug mills, and in every other mill properly so called. I remember," he adds, "frequently when a boy to have trodden with one heel on a piece of soft brick, or of dry old mortar, which was firm enough to bear the weight of my body, unimpaired; but, on giving my body a swing round with my other foot, I have instantly reduced it to powder. The action in this case is very obvious the weight of my body confined the piece of brick firmly to the ground my heel was also pressed by the same weight firmly upon the brick one part of the brick therefore remaining confined to the ground and the other part being carried round by my heel, the brick of course was torn asunder and reduced to powder. This I conceive is a simple elucidation of the difference between pressing and grinding, and thus is the difference of the effects on the materials of our roads, produced by the use of upright cylindrical wheels, which act only by pressure; by the use of conical wheels, which by their constant twist, act also by grinding; and by very convex roads, by which means the wheels of all carriages, except such as occupy the crown of the road, whether cylindrical or otherwise, act in the same twisting, sliding and grinding manner (Obs. on Roads, &c 1812.)*

3578. *By the incision of objects passing along roads, we allude to the dividing operation of wheels, which, independently of their effect as moving levers, act also as moving wedges, or perhaps, more properly, as endless saws, in forming ruts or deepening such as are already made. Flat roads, so as to produce less temptation to follow in the middle track, watchful repair and broad wheels, are the mitigators of this description of wear.*

3579. *Water is one of the most serious causes of the wear of roads. As we have already observed (3572.), it acts, aided by pressure like gunpowder in rending the surface of bodies. Frozen, it acts exactly in the same manner and when it has penetrated deeply into a stratum of materials, a thaw produces their entire derangement. Mud is formed in consequence of the presence of water and dust or earth and acts as a sponge to retain it, and perpetuate its bad effects. A well composed and thoroughly compressed substratum will not imbibe water, unless it rests in ruts or other hollows. To form such a stratum, therefore, and obliterate all hollows as soon as they appear and to remove mud and dust, are the palliatives of this mode of wear. On such a road heavy showers may do good, by washing away the earthy particles, dung, and other injurious earthy or vegetable matters.*

3580. *Wind is mostly a favourable agent to roads, by drying them and blowing off the lighter dust but in some cases, in very exposed situations, it has been known to blow the dust into heaps, and sometimes to carry off larger particles than could be spared. The last evil is fortunately rare the other only requires the removal of the accumulated heaps of dust.*

#### SOURCE 2 *M'Adam's Theory and Practice of Road-making*

3581. *M'Adam agrees with other engineers, that a good road may be considered as an artificial flooring, forming a strong, solid, smooth-surfaced stratum, sufficiently flat to admit of carriages standing upright on any part of it, capable of carrying a great weight, and presenting no impediment to the animals or machines which pass along it. In forming this flooring, M'Adam has gone one step beyond his predecessors, in breaking the stone to a smaller size than was before practised, and in forming the entire stratum of this small-sized stone. By the former practice a basement of large stones is first laid then stones of a degree smaller and, lastly the least size on the surface. It is in this point of making use of one small size of stones throughout the stratum, that the originality of M'Adam's plan consists, unless we add also his assertion, "that all the roads in*

the kingdom may be made smooth and solid in an equal degree, and to continue so at all seasons of the year " It is doubted by some, whether this would be the case in the northern districts at the breaking up of frosts, and especially in the case of roads not much in use, and consequently consisting of a stratum less consolidated, and more penetrable by water M Adam, probably has much frequented public roads in view " The durability of these," he says, " will, of course, depend on the strength of the materials of which they may be composed but they will all be good while they last, and the only question that can arise respecting the kind of materials is one of duration and expense, but never of the immediate condition of the roads " (*Remarks on Roads, &c* p. 11 ) The following observation of Marshall is worthy of remark, as tending to confirm, to a certain extent, the doctrine of M Adam — ' It may seem needless to repeat, that the surface of a road which is formed of well broken stones, binding gravel, or other firmly cohesive materials, and which is much used, presently becomes repellant of the water which falls upon it no matter as to the basis on which they are deposited, provided it is sound and firm enough to support them.

3582. *M'Adam's theory of road-making* may be comprised in the following quotation from his *Report to the Board of Agriculture* (vol vi p. 46.) — Roads can never be rendered perfectly secure until the following principles be fully understood admitted, and acted upon namely that it is the native soil which really supports the weight of traffic that while it is preserved in a dry state it will carry any weight without sinking, and that it does, in fact, carry the road and the carriages also that this native soil must previously be made quite dry and a covering impenetrable to rain must then be placed over it to preserve it in that dry state that the thickness of a road should only be regulated by the quantity of material necessary to form such impervious covering and never by any reference to its own power of carrying weight. There are some exceptions to this rule a road of good naturally binding gravel may be laid on a sub-bed of bog earth, which, from its tenacity will carry all kinds of carriages for many years."

3583. *The erroneous opinion so long acted upon, and so tenaciously adhered to* that by placing a large quantity of stone under the roads, a remedy will be found for the sinking into wet clay or other soft soils or in other words, that a road may be made sufficiently strong artificially, to carry heavy carriages though the subsoil be in a wet state, and by such means to avert the inconveniences of the natural soil receiving water from rain or other causes has produced most of the defects of the roads of Great Britain. At one time M Adam had formed the opinion that this practice was only a useless expense but experience has convinced him that it is likewise positively injurious.

3584. *If strata of stone of various sizes be placed as a road, it is well known to every skilful and observant road maker* that the largest stones will constantly work up by the shaking and pressure of the traffic and that the only mode of keeping the stones of a road from motion is, to use materials of a uniform size from the bottom In roads made upon large stones as a foundation, the perpetual motion, or change of the position of the materials, keeps open many apertures, through which the water passes.

3585. *Roads placed upon a hard bottom, it has also been found, wear away more quickly than those which are placed upon a soft soil* This has been apparent upon roads where motives of economy or other causes have prevented the road being lifted to the bottom at once the wear has always been found to diminish, as soon as it was possible to remove the hard foundation It is a known fact, that a road lasts much longer over a morass than when made over rock The evidence produced before the committee of the House of Commons showed the comparison on the road between Bristol and Bridgewater to be as five to seven in favour of the wearing on the morass, where the road is laid on the naked surface of the soil against a part of the same road made over rocky ground.

3586. *The common practice on the formation of a new road, is, to dig a trench below the surface of the ground adjoining and in this trench to deposit a quantity of large stones* after this, a second quantity of stone, broken smaller generally to about seven or eight pounds weight these previous beds of stone are called the bottoming of the road, and are of various thickness, according to the caprice of the maker and generally in proportion to the sum of money placed at his disposal. On some new roads, made in Scotland in the summer of 1819, the thickness exceeded three feet. That which is properly called the road is then placed on the bottoming by putting large quantities of broken stone or gravel generally a foot or eighteen inches thick at once upon it. Were the materials of which the road itself is composed properly selected prepared, and laid, some of the inconveniences of this system might be avoided but in the careless way in which this service is generally performed, the road is as open as a sieve to receive water, which penetrating through the whole mass is received and retained in the trench, whence the road is liable to give way in all changes of weather A road formed on such principles has never effectually answered the purpose which the road-maker should constantly have in view namely to make a secure level flooring over which carriages may pass with safety and equal expedition at all seasons of the year

3587 *An artificial road in Britain is only required to obviate the inconvenience of a very unsettled climate. Water with alternate frost and thaw, are the evils to be guarded against; consequently, nothing can be more erroneous than providing a reservoir for water under the road, and giving facility to the water to pass through the road into this trench, where it is acted upon by frost to the destruction of the road. As no artificial road can ever be made so good and so useful as the natural soil in a dry state it is only necessary to procure and preserve this dry state of so much ground as is intended to be occupied by a road.*

3588. *The first operation in making a road should be the reverse of digging a trench. The road should not be sunk below, but rather raised above, the ordinary level of the adjacent ground. Care should at any rate be taken, that there be a sufficient fall to take off the water, so that it should always be some inches below the level of the ground upon which the road is intended to be placed. This must be done, either by making drains to lower ground, or if that be not practicable, from the nature of the country then the soil upon which the road is proposed to be laid must be raised by addition, so as to be some inches above the level of the water.*

3589 *Having secured the soil from under-water, the road-maker is next to secure it from rain water by a solid road made of clean dry stone or flint, so selected, prepared, and laid, as to be perfectly impervious to water and this cannot be effected unless the greatest care be taken that no earth, clay, chalk, or other matter that will hold or conduct water, be mixed with the broken stone which must be so prepared and laid, as to unite with its own angles into a firm, compact, impenetrable body.*

3590. *The thickness of such road is immaterial, as to its strength for carrying weight. This object is already obtained by providing a dry surface, over which the road is to be placed as a covering or roof to preserve it in that state. Experience having shown, that if water passes through a road, and fills the native soil, the road, whatever may be its thickness, loses its support, and goes to pieces. In consequence of an alteration in the line of the turnpike road, near Rowham Ferry, in the parish of Ashton, near Bristol, it has been necessary to remove the old road. This road was lifted and re-laid very skilfully in 1806 since which time it has been in contemplation to change the line, and consequently it has been suffered to wear very thin. At present it is not above three inches thick in most places and in none more than four. Yet on removing the road, it was found that no water had penetrated, nor had the frost affected it during the winter preceding and the natural earth beneath the road was found perfectly dry.*

3591 *Several new roads have been constructed on this principle within the last three years. Part of the great north road from London, by Hoddesdon, in Hertfordshire two pieces of road on Durdham Down, and at Rowham Ferry near Bristol with several private roads in the eastern part of Sussex. None of these roads exceed six inches in thickness, and although that on the great north road is subjected to a very heavy traffic (being only fifteen miles distant from London), it has not given way nor was it affected by the late severe winter (1819-20), when the roads between that and London became impassable, by breaking up to the bottom, and the mail and other coaches were obliged to reach London by circuitous routes. It is worthy of observation that these bad roads cost more money per mile for their annual repair, than the original making of this useful new road.*

3592. *Improvement of roads, continues M. Adam, 'upon the principle I have endeavoured to explain, has been rapidly extended during the last four years. It has been carried into effect on various roads, and with every variety of material, in seventeen different counties. These roads being so constructed as to exclude water consequently none of them broke up during the late severe winter (1819-20) there was no interruption to travelling, nor any additional expense by the post-office in conveying the mails over them, to the extent of upwards of one thousand miles of road.'*

3593. *On M. Adam's theory the only practical road-maker who has published his opinion is Paterson of Montrose. He says (Letters and Communications, &c. 1822) "These certainly ought to be considered as the grand first principles of road-making. He commends M. Adam's reasoning on these principles but objects, as we think with reason, to his drainage of three or four inches, as being insufficient. He adds, however, that though he considers M. Adam's system as erroneous and defective in draining and preparing the road for the materials, yet, in regard to the materials themselves, the method of preparing and putting them on, and keeping the road free from ruts by constant attention, has his entire approbation. These principles, however, he adds, "are not new; but have been acted upon before. In regard to small breaking, he certainly has had the merit of carrying that mode to greater extent than any other individual that I have heard of, and the beneficial effects arising from it have consequently been more extensively seen and experienced." (Letters on Road-making, p. 42.)*

**SUMMARY 3. Road-making, as treated of and practised by various eminent Engineers and Surveyors.**

3594. *The subject of forming a road may be considered as to breadth, drainage, fences, base of the hard materials or artificial stratum, upper line of the stratum, composition of the stratum, size of the materials, laying, and compressing.*

3595. *With respect to breadth, the site of every public road, according to Marshall, ought to be sufficiently ample to admit of its division into three travelable lines namely*

1. *A middle road of hard materials, for carriages and horses in winter and wet seasons*
2. *A soft road, formed with the natural materials of the site, to be used in dry weather to save the unnecessary wear of the hard road, and to favour the feet of travelling animals, as well as for the safety ease, and pleasantness of travelling in the summer season and*
3. *A commodious path, for the use of foot passengers, at all seasons. There are few roads, even in the environs of populous towns, so public as to require a hard road of more than two statute poles (thirty three feet) in breadth and every public road ought, under ordinary circumstances, to have a line which is travelable at any season, and of ample width to permit two carriages to pass each other with freedom and safety. This ample width let us set down at one statute pole. In deep clayey districts where hard materials are difficult to be procured a single road, of half a pole in breadth, with dilations at proper distances, to let carriages pass each other, may in many remote situations, be advisable.*

3596. *Seventy feet in width seems to be considered by Farey, Walker Telford, and most engineers, as sufficient near the largest towns and in the case of the metropolis and some others, they consider that ten or twenty feet in width may be paved. The London Commercial road, executed under the direction of Walker is seventy feet wide; ten feet on each side are occupied as footpaths, twenty feet in the centre are paved for heavy carriages, and there are fifteen feet of gravel road at each side for light carriages and saddle horses. This road has been executed for sixteen years, and has given the greatest satisfaction but Walker thinks that considerable improvement would be found from paving the sides of a road, upon which the heavy traffic is great in both directions, and leaving the middle for light carriages. The carmen or drivers, walking upon the footpaths or sides of the road, would then be close to their horses, without interrupting or being in danger of accidents from light carriages, which is the case when they are driving upon the middle of the road and the unpaved part being in the middle or highest part of the road, would be more easily kept in good repair. But unless the heavy traffic in both directions is great one width, say ten or twelve feet, if very well paved, will be found sufficient and in this case the paving ought to be in the middle of the road. The width of many of the present roads is, besides, such that ten or twelve feet can be spared for paving, while twice that width would leave too little for the gravelled part. Although the first cost of paving is so great, he does not think that any other plan can be adopted so good and so cheap in those places where the materials got in the neighbourhood are not sufficient for supporting the roads. A coating of whinstone is, for instance, more durable than the gravel with which the roads round London are made and repaired, but much less so than paving although the freight and carriage of the whinstone, and of the paving stones, which form the principal items of the expense, are nearly the same.*

3597. *Roads ought to be wide and strong, Edgeworth observes in proportion to their vicinity to great towns, mines, or manufactures. As they approach the capital, they should be wider and stronger than elsewhere. When a number of roads leading to a great city combine and fall into one, the road from that junction should be proportionably solid and capacious. Near the capital the width of roads is however often restricted by buildings, that cannot with propriety be suddenly removed but every opportunity for removing these buildings, and for widening the road should be attended to, and no future buildings or encroachments should be allowed. And, though in some cases it appears reasonable to permit the erection of new buildings, and the making new plantations, nearer than thirty feet from the centre of a road, upon condition that security should be given to the public for the constant preservation of the road that is thus injured it is, however far safer to prohibit what is injurious to public convenience, than to compromise with individuals cases of private hardship may and must occur but it is part of the true glory of Britain that there exists no exemption in our laws in favour of the rich.*

3598. *Proportioning the breadth of roads to the traffic for which they may be employed is not sufficiently attended to. In remote places, where there is but little traffic, the waste of ground, occasioned by superfluous width of roads, is an error of considerable magnitude. There are many places where roads of twenty feet in breadth would suit the public convenience, as well as if they were twice as broad. Now it is clear, that if a road is one pole or perch wider than is necessary there is a waste of 390 perches in a*

miles, equal to two acres of ground, which, at the rate of three pounds per acre, would, if the road had been once well made, keep half a mile of such road as is here alluded to in good repair.

3599. *The breadth of the road and the width of the metals, according to Paterson,* should depend on circumstances different from the former. For a few miles in the vicinity of such cities as London or Edinburgh, the most proper breadth at which a road should be formed, is properly from sixty to seventy feet, and the metals from twenty five to thirty five feet. While in the neighbourhood of such towns as Newcastle or Perth, it will be sufficient that it be formed forty feet broad, and that the width of the metals be about eighteen or twenty feet. These are the breadths presumed to be the most eligible in such situations. But rules cannot be given to suit every situation the breadth ought to be regulated according to the extent of the run of commerce, or traffic, upon the road. As a general rule, however for public roads over the different counties of Great Britain, he 'should suppose the following might, in most cases be adopted. Take, for instance, the road betwixt Edinburgh and Glasgow or betwixt Edinburgh and Aberdeen by the way of Dundee. These roads are formed in general from thirty five to forty feet wide and the breadth of the metals is from fourteen to sixteen feet, for the most part. Such roads as these would be found to answer very well in general over the kingdom." A breadth sufficient for the general purposes of country travelling according to M Adam, is sixteen feet of solid materials, with six feet on each side formed of lighter materials. The Bristol roads, he says, are made with stone about the width of sixteen feet.

3600. *The increased breadth which is now given to our public roads, according to Stevenson* independently of the safety and convenience of the traffic, is favourable to the more speedy drying of the road by evaporation and is calculated to render less injurious the rising growth of the hedgerows, and the ultimate erection of buildings along the line. 'The highways or great lines of road should, in no instance, be formed of a less breadth than forty feet, and the metal bed not less than eighteen feet broad, with at least one footpath of five feet in breadth along the side especially within a few miles of all towns and villages. It would be difficult to give any scale of breadths for public roads, the local circumstances of which vary so much. But, without presuming to be fastidious, we notice, that, within six or eight miles of all large cities or towns, the approaches should not be formed at less than sixty feet between the fences. In such situations the whole breadth should be metalled, or laid with broken stones. In the vicinity of towns of about 50,000 inhabitants, the breadth should be at least fifty feet between the fences, and be in like manner metalled from side to side. Where the population does not exceed 30,000, the statutory breadth of forty feet may be adopted, the metalling being still continued of the whole breadth, with paved side-drains. At intermediate distances, where it is not thought advisable to have the metal of a greater breadth than eighteen feet, the compartments between the metal bed and the side-drains may be laid with gravel or chips of stone to the depth of not less than half the thickness of the central part of the road. In the vicinity of London, and the capitals of Dublin and Edinburgh and other great towns, as Glasgow, Manchester, Liverpool, &c it would be desirable that the principal approaches were at least seventy feet in breadth, fully metalled between the side-drains which ought to be neatly formed, and paved, and the roads provided with a footpath on each side." (*Ed. Encyc. art. Roads.*)

3601 *Narrow roads,* it is judiciously observed by Fry are almost always in bad condition which is to be accounted for from the circumstance of every carriage being obliged to go in the same ruts and as each rut is generally only six inches wide, *one foot* of the road only is worn by the wheels instead of the whole breadth of it which would be the case if the road were of a proper width, and if it were well constructed. If a road be laid out, from twenty to thirty feet wide, so flat as that a carriage may stand nearly upright on every part of it, and if moderate care be taken by the surveyor to prevent the first formation of ruts, such a road will be worn by the wheels nearly alike on every part of it provided also that the ground on each side, for at least four or five feet, be moderately flat, so as not to excite fear in the drivers of carriages but if there be deep ditches close to the sides of the road, or if the circumjacent land fall off very abruptly to the depth of two or three feet, whereby fear of approaching the edges would operate on the minds of the drivers, every driver will instinctively avoid the danger on either hand and a road so circumstanced will, in spite of any care of the surveyor inevitably be worn into ruts in the middle. There is a remarkable instance of this kind in a piece of road on *Durdham Down, near Bristol*. This road is a *carrieway* over a piece of soft ground and although it is from twenty to twenty five feet wide, yet as the ground falls away abruptly on both sides of it, it has been found impossible, for more than twenty years past, to his knowledge, to prevent deep ruts being formed along the middle of it notwithstanding the Down itself consists of hard limestone, and the other roads upon

consolidated as to form a solid body, and to be impervious to water. Bubbles, however, the Down are as fine and even as any roads in England. Were this piece of road widened out on each side, in an easy slope of about five feet, by rubbish of any kind, and by the scrapings of the road itself, whereby the instinctive operation of fear of approaching the sides of the present road would be obviated, that piece of road would be found to wear as fairly as the other roads on the same Down.

3602 *In regard to the drainage of roads*, Marshal directs to examine the site in every part, to ascertain whether offensive waters lodge beneath it or quacksands, and land springs, which break out in a wet season. If defects of this kind be found, effectual drains are to be run up to them from the ditches or outer side drains of the site.

3603. *When roads run through marshy ground*, Edgeworth observes, "the substratum must be laid dry by proper drainage and where the road is liable, from the flatness of the country, to be at times under water the expense of raising it above the water must be submitted to in the first instance. All drains for carrying off water should be under the road or at the field side of the fences, and these drains should be kept open by constant attention and should be made wide at the outlet."

3604 *The method of draining which Paterson has found the most effective is thus described* — Before the materials are put on run a drain along the middle of the road, all the way from two to three feet deep then fill it with stones up to the surface making those at bottom of a pretty good size, and those at the top fully as small as the road materials. And, in order that the quantity of stones used for the said drain may be as little as possible and every way to save expense it may be made as narrow as it can possibly be dug. From this leading drain make a branch here and there to convey off the water to the canals on the sides of the road." This mode of draining he has found, from experience to be so beneficial that a road so drained would be better and more durable with eight inches, than it would otherwise be with twelve inches of materials and not only so but that on such a road there would be a saving on the incidental repairs, ever afterwards, of about one half of the labour and at least one third of the material.

3605 *All moisture from under the road materials must be carried off by such drains*. Then if the materials are properly broken, they will become so firm and solid that little or no water will get through them and if it should this drain would carry it away. So that, under any view of it, the utility of these drains must be very apparent but when we consider that, to have the ground under the road materials perfectly dry is to insure a good road, these drains become indispensably necessary and the expense is a mere trifle. There are two miles of road, which were made on this plan under Paterson's direction, which have stood all the winter rains without injury and which promise to make one of the finest roads in the kingdom. There is another road of ten miles, that he has lately planned, for the greater part of which he has specified two such drains, running parallel to each other and five feet apart and he would even recommend three or four parallel drains where there is a great breadth of metals, except where the road is formed over dry sand or open gravel. Although the effect of such drains will be at all times beneficial to the road in time of a thaw after there have been a few weeks of frost, it will be peculiarly so. In frost, the surface of the road though wet before, becomes dry the water being absorbed by the road, or otherwise condensed by the frost but no sooner is this succeeded by a thaw than the absorbed or condensed water again makes its appearance all over the surface of the road. This is the time that these drains are so peculiarly beneficial.

3606. *When such drains are wanting* the road on the return of a thaw throws up to the surface all the water it had imbibed and in many places, the materials, swelling up become quite loose and open. This is a natural consequence, where the material is not thick, and where the soil under the road is not perfectly dry but where a road is dried in the way described, it will be uniformly seen that the water instead of spewing out on the return of a thaw is sucked in by the drains, so leaving the surface of the road quite dry. It may be observed, that at such times the places of the road where a few roads of such drain had been introduced, presented to the eye, at a quarter of a mile distant quite a contrast to the other parts of the road the one opaque and dry from the moisture being sucked in the other all wet and glistening, from its being thrown out to the surface (*Paterson's Letters, &c.* 44. 48 84.)

3607 *Thorough drainage* Stevenson observes should pervade the whole system of the formation of roads. The smaller drains, connected immediately with the road, must vary in their number direction and description, according to the judgment of the engineer. They consist of what are technically termed *box* and *rumb/ing* drains the former of which are built, and the latter consist of a stratum of rubble stones, simply thrown into an excavation made for their reception, through which the moisture is allowed to percolate. Where the road is to be made through a boggy or marshy soil, which is generally pretty level, the opportunities for drainage are less obvious, nor

is this so material, as ground of this description is capable of containing a great quantity of water without endangering the flooding of the road. In such situations it also fortunately happens that land is seldom of much value, and therefore, in making a road through a morass, a much greater breadth should be included between the lateral drains than where the ground has an undulating surface. Attention should also be paid to cut the ditches of a moderate depth, as the tenacity of such soils depends upon their being kept in a somewhat moist state. If a section of such ground be exposed to the sun and air, by deep side cutting, it soon pulverises, and loses its elasticity, when the level of the road falls, and its surface gets into disorder. The drainage of a road should rather be made across than in a lateral direction, as being less apt to be injured by the traffic upon it." (*Ed. Encyc. art. Roads*.)

3608. *The side drains* Telford and Walker recommend to be, in every instance, on the field side of the fence. In cases, Telford observes, where a road is made upon ground where there are many springs, it is absolutely necessary to make a number of under and cross drains to collect the water and conduct it into the side drains, which should always be made on the field side of the fences. The orifices of these cross drains should be neatly and substantially finished in masonry.

3609. *The surface-drains, or water-tables*, should be made a few inches lower than the side of the road, and of the common width of a spade at the bottom and they should have frequent cross drains under the path and fence, back into the outer side drain.

3610. *Water-tables across the road* become requisite in some cases, as in flat roads on a steep slope. These should always be made at right angles to the road, with their sides gently sloping, to occasion as little obstruction to carriages as possible. In some few cases, where roads are liable to floods, or are deficient in drainage, these surface-tables may require to be made of a considerable breadth, and paved. In this case Greig (*App. to Structures on Road Police*, p. 219) directs to lay six feet at the bottom of it flat, and twelve feet on each side to rise at the rate of one inch in the foot, which will make the depth one foot; and from the rise, no carriage will feel any jerk or shake in passing it. The pavement should be made of hammered stones, of nearly equal depth, each stone from nine to twelve inches long on the surface, and four to eight inches broad, and nine inches to a foot deep. The under-side to be flat in the under face, and not of an irregular or angular under-surface, as in that case it would not be solid.

3611. *Bridges and embankments, of different degrees of magnitude* are required in all lines of road of any length or variety of surface. The subject of large bridges we leave to the engineers, no department of their art having attained higher perfection of which the wonderful erections by Telford, in almost every mountainous district in Britain, may be referred to as proofs. We confine ourselves entirely to such stone arches as may be designed by road-surveyors, and built by country masons. In many cases, cast-iron might be substituted for stone with economy and advantage as to waterway. But though the principle of constructing both cast and wrought iron bridges is perfectly simple, the execution, and especially the putting up requires more skill, and are attended with much more risk than the erection of either stone or timber bridges.

3612. *One low arch* is in general the most desirable description of common road-bridges. But most of the country bridges, as Clarke observes, consist of several small, high, semicircular arches where there is a single arch, the stream passes without interruption. If there are two or three in the same situation, the space through which the water is to pass is necessarily contracted by the width of the piers. Ice and large bodies carried down by floods, frequently stop up the small arches, and the accumulated water carries away the bridge, but if such accidents should not happen, the constant currents rushing against those piers wash out the mortar, loosen the stones, and very soon undermine the work, if not extremely well put together which is seldom the case. Unless the river or stream is narrow, or the banks very high, a semicircle is an inconvenient shape for an arch, it has been adopted on account of the insufficiency of the abutments, and because the pressure is more perpendicular. But scientific engineers, in all countries, now construct their bridges with wide openings, and make the arches either semi-ellipses, or segments of large circles—so that the space above the highest floods is comparatively little, and the ascent over the bridge inconsiderable. In country bridges in Ireland, Clarke continues, the foundations are invariably, and often intentionally defective: the mason considers himself an honest man, if his bridge lasts seven years; whereas, from the durability of materials in that country it ought to endure for ages. Whatever is under water is out of sight, and is generally composed of loose stones, thrown promiscuously together, on which the masonry is erected, and all the pains and expense are bestowed on the cutwaters and wings, when the heaviest stones, and those accurately jointed, ought to be laid in the foundations. The greatest attention should be paid to the quality of the materials: the stones should be large, and laid in level courses, in the best mortar composed of sharp sand, free from loam, and quicklime, accurately mixed together, the coping of the parapet is generally so slight, that it is

broken down as soon as built, and the entire parapet quickly follows; — it ought to be of large heavy stones, roughly hewn, and there should be substantial quoins at the ends of the parapets with an immovable stone over them.

3613. *Arches not exceeding eight feet span may be semicircular; tunnels not exceeding eighteen inches wide may be covered with strong flags, and either flagged or paved under and there ought to be across either end a deep long stone, sunk below the surface of the current, and under the walls, to prevent the water from undermining the work; if the stones are square and heavy, these small conduits may be built without mortar, except at the ends.*

3614. *In building tunnels or arches across a road in a flow-bog, great pains must be taken with the foundation, or the whole structure will inevitably sink the building of these should be deferred as long as possible, till the peat has subsided, and has obtained a tolerable consistence, then make an opening equal to the whole work, and sink it eighteen inches below the intended bottom of the arch or gullet collect a quantity of black-thorn bushes, and tie them in faggots of the same size place these in regular courses in the direction of the road, and lay across them a platform of strong plank three inches thick, the whole length and width of the intended mason work; on this build your arch, and make an allowance in the height of the abutments for sinking. Wherever walls are necessary to support banks, and prevent their crumbling down upon the road, if large even stones can be procured, they will not require any mortar when mortar is used, there ought to be a great many apertures in the work to give vent to the water otherwise the pent-up moisture from behind will push out the wall. In many cases, where embankments can be made of earth and soda, they are to be preferred to masonry, which is extremely expensive at the commencement, and very perishable for mortar soon loses its cementing quality when exposed alternately to frost and damp.*

3615. *Draining the side of a road on a flow-bog according to Clarke, is a tedious operation, and often requires some years. A single drain at each side will not be sufficient, as the water from the adjacent moss would fill it up as fast as it was made. Lay out the road here sixty feet wide, which will allow for the banks when the whole shall be finished make a drain at each side six feet wide, and at a distance of fifteen or twenty feet more, parallel drains of the same width. If the interval between the parallel drains be afterwards cut away regularly for fuel, it will tend still to the condensation of the moss.*

3616. *Open drains in the case of ground liable to sink or to moulder down by frost, ought to be made very much sloped on the sides, especially the side next the road, otherwise, after repeated scouring out, the road will be found to have sunk at the sides — a very common case, and highly injurious in the case of narrow roads. Whenever this tendency to sink is observed, it should be made up by the scrapings of the road or by other materials. Roads made over bogs and artificial mounds are particularly liable to sink at the sides which should be immediately counteracted to prevent the bad consequences.*

3617. *Fences along the sides of roads are essential in all enclosed countries and all engineers and road-makers agree that they should never be allowed to rise of a greater height than what is necessary for a fence. To give free admission to the sun and air by keeping the fences low, Marshal considers as providing an unexpensive, yet most accurate, method of cleaning roads — incomparably more so than washing or scraping. The legislature, Edgeworth observes, has limited, in several instances, the height of hedges to five feet but this limitation is neglected or evaded. Even were it strictly adhered to, it would not be sufficient for narrow roads the hedges would be still too high for it is the sweeping power of the wind which carries off dust in dry weather and which takes up moisture in wet. In fact, roads become dry by evaporation and when they are exposed to the sun and wind, the effect of heat and ventilation is more powerful than any surface drainage that could be accomplished.*

3618. *Walker observes, that the advantage of having the hedge next the road consists in its greater safety to the traveller, particularly if a ditch of any considerable depth is necessary, and in the hedge being supported in its growth from the ground under the road, without drawing upon the farmer's side of the ditch.*

3619. *The fences, Telford observes, form a very material and important subject, with regard to the perfection of roads they should in no instance be more than five feet in height above the centre of the road, and all trees which stand within twenty yards from the centre of it ought to be removed. I am sure that twenty per cent. of the expense of improving and repairing roads is incurred by the improper state of the fences and trees along the sides of it, on the sunny side more particularly this must be evident to any person who will notice the state of a road which is much shaded by high fences and trees, compared to the other parts of the road which are exposed to the sun and air. My observations with regard to fences and trees apply when the road is on the same level as the adjacent fields but in many cases on the most frequented roads of England, more stuff has been removed from time to time than was put on the surface of the road is consequently sunk into a trough or channel from three to six feet below the surface of*

the fields on each side here all attempts at drainage, or even common repairs, seem to be quite out of the question, and by much the most judicious and economical mode will be to remove the whole road into the field which is on the sunny side of it. (*Mem. before the House of Commons, &c.*)

3630. *Is the junction of roads, whether of a by-road with a principal road, or of two by or principal roads, their respective levels ought, if possible, to be the same, and the materials ought to be rather broader than usual at the point of turning.* In like manner the communication of fields by gates ought to be carefully managed, so as not to injure the public road, the footpath, the water-table, or the inner drain. All gates should open inwards to the fields, and not to the road.

3631. *That plantations of trees should not be made close to roads, all are agreed.* What the distance ought to be must depend on the elevation of the country the soil and sub-soil, the breadth of the road its direction, whether the plantation is to be made on the north or south side of the road, its thickness, kind of tree, &c. An elevated situation is always more exposed to the wind than a level or hollow and a dry soil and subsoil will always, other circumstances being the same, have a favourable effect on the roads which pass over them. A broad road, and a road winding in its direction, have chances of the direct influence of the sun and wind, according to the width of the former and obliquity of the latter a road running north and south though planted closely on both sides, will enjoy the sun during a part of every day in the year one running east and west, planted on the south side with trees forty feet high, will enjoy no sun but through the interstices of the branches during the three winter months. Supposing the average height of the sun from ten to two o'clock during these three months to be 30 degrees, then a tree forty feet high will throw a shadow every day during that period, upwards of 100 feet long, which may show that no plantation should be made nearer the south sides of roads than 80 or 100 feet. On the north-east and north-west sides, they may be nearer according to the elevation and natural tendency to dryness of the site, and also taking into consideration whether the trees are evergreens, and with or without underwood. The least injurious trees are single rows trained to high stems, properly pruned in, or forshortened.

3632. *The preparation of the base of a road, for the reception of the metals or hard materials, is a matter of primary importance.* Marshal, Edgeworth, and some other writers, with almost all practical men, seem to have entertained much less enlightened notions on this subject than M'Adam.

3633. *Marshal's preparation* consists in striking off the protuberances and filling up the hollow parts the footpath and the higher side of the soft road being raised with the earth which is required to be taken off the bed of the hard road, whose base or foundation ought to be formed with peculiar care. Every part is required to be firm and sound, dry earth, or hard materials, being rammed into every hollow and yielding part. In a dry situation, as across a gravelly or stony height, little more, he says, is required, than to remove the surface mould, and lay bare the rock or bed of gravel beneath it and then to give the indurate base a round or a shelving form, as the lying of the ground may require. In this way a travelable road may be made, and kept up, at one tenth of the expense incurred by the ordinary practice in this case which is to gather up the surface-soil into a ridge, and, on this soft spongy bed, to lay coat after coat, some hard materials, fetched perhaps from a distance.

3634. *A soft bed is now found by far the best* and M'Adam has proved, in the case of part of the road between Bridgewater and Crows, that a stratum of hard materials covering a morass will last longer than a similar stratum laid on rock indeed, it may be questioned whether a properly made road on a bog, which yields by its elasticity will not last longer than one on a firm surface. We have been told by a gentleman of some experience in road-making, that in Ireland this is actually found to be the case. "Precisely" as Fry observes, "for the same cause that a stone placed upon a woolpack would bear a greater pressure before it would be broken, than it would if placed on an anvil." (*Essay on Wheel Carriages, &c. App. 129.*)

3635. *Covering the base of an unsound road with faggots, branches, furze, or heath* is recommended by Edgeworth. Flat stones, he adds, if they can be had, should then be laid over the faggots, and upon them stones of six or seven pounds weight, and, lastly, a coat of eight or ten inches of pounded stone. If the practicability of consolidating a mass of stones each of six or eight ounces weight and under so as to act as one plate or flooring, be admitted, then the faggots and flat stones must at least be useless and the stones of six or seven pounds weight injurious because, whenever the upper stratum had worn down a few inches, some of these stones, and eventually the greater number would be worked up to the surface, and the road destroyed, or put in a state to require lifting, breaking, and relaying.

3636. *A basement of trees, bushes, or bushes, is made use of by Walker when the ground is very soft.* They carry off the water previously to the materials of the road being so

should not be used, unless they are so low as always to be completely moist. When they are dry and excluded from the air they decay in a very few years, and produce a slaking in place of preserving the road. A thickness of hard chalk has been recommended for the same purpose: the chalk, mixing with the gravel or stones, becomes concreted, and presents a larger surface to the pressure. It is alleged on the other hand, that chalk is one of the worst materials for roads, as it absorbs water, which, when frozen, never fails to break up the road.

3627 *The base of the road is constructed by Telford and Stevenson of an elliptical form* if it is upon clay or other elastic substance which would retain water, Telford would recommend to cover the whole bottom of the road with surface soil in cases where the natural shape of the ground admits, he would not remove the original surface and, where there are inequalities, he would fill them up with surface soil, so as to cut off all connection with clay.

3628. *In forming the base of a road on a flow-bog*, Clarke directs to strip the heathy sods (tussocks) off the whole surface of the side-drains, and place them with the heath uppermost on the space intended for the road or if a sufficiency of brushwood or furze can be procured, it will answer still better. Proceed to let off the water at the lowest ends of the drains, leaving an open channel in the middle of each. After the water has run off for some time, throw off another spit and repeat this operation month after month, till the space for the road becomes compact and dry and be sure to keep it in that state by cleaning the drains frequently. There should be eight or ten inches of tough clay laid over the tussocks or brushwood, which will be greatly the better of being consolidated by rollers. This part of the road may be left rather higher in the centre than the other parts, to allow for settling. There is no situation where it is more difficult to make a good road than through a flow-bog but, if once made well, it is the most permanent of all roads, and, from its elasticity the most easy to horses.

3629. *In forming the base of a road on this moor* the whole of the peat should be removed from the space on which the road is to be made for, if allowed to remain between the hard subsoil and the small stones, the weight of carriages would press down the latter, force up the black peat through them and totally spoil the road. This happens only where there is a thin soft, peaty stratum between two hard bodies for in deep bog, the elasticity of the foundation yields to the superficial pressure, and contributes to the durability of the materials after this has been so removed, the surface, when formed and drained, will be ready for the road materials.

3630 *In forming the base or metal-bed*, Paterson observes, it is common to cut it to the exact breadth and depth of the metals, and to make it quite flat in the bottom, or level from the one side of the metals to the other. Supposing this metal-bed to be formed fourteen feet broad, and nine inches deep, on a breadth of fourteen feet, the metals would require to be about three inches higher in the middle than on the sides. In this case, then, they would be nine inches deep on the sides and twelve on the middle and as it is evident that the middle of the road, where the metals are deepest, is not subjected to so much waste from the tread of the horses' feet, as that nearer the sides is from the grinding of the wheels, this is, therefore a waste of metals on the middle of the road. But this is not the greatest evil of which I complain the metal-bed being cut into the solid ground, and flat in the middle, and having the earth on each side about nine inches higher than it, — this, upon any other ground than that of dry sand or gravel, forms a bed for retaining the water, as well as for holding the metals, which often deluges the middle of the road with mud or gutters, when it might be prevented. I would therefore propose, that a metal bed of fourteen feet broad should, instead of being level have a rise in the middle of at least four inches which will make a declivity from the middle to each side of nearly two inches in the yard. Then, supposing the surface of the metals to have the same shape as mentioned above, viz three inches higher on the middle than on the edges, the metals on the sides will be the same depth as formerly mentioned, namely nine inches but instead of twelve inches on the middle, they will then only be seven inches deep, which makes a saving of five inches. This saving of five inches on the middle, or two inches and a half on the whole breadth of the metals, is very considerable but this is not the only benefit arising from this mode of procedure. The metal-bed, having a slope from the middle to each side of the road, so far from retaining the water, runs it off from the middle and this will be of more service in keeping the road in good order ever afterwards, than if you were to put three or four inches more of additional depth to the metals on the common plan. This appears to me to carry so much of common sense on the face of it, that I am surprised it has not long ere this time been generally adopted. Here Paterson seems to infer that water may or rather does, penetrate the stratum of metal to the base, which, in properly made roads, will at least not often be the case. The argument of a saving in materials is quite sufficient to justify him and Telford in adopting the elliptical form for a base.

3631. *A soft base* is always preferred by M<sup>r</sup> Adam, who drains effectually, and puts no

intervening material between the metals and the earth, even if it were a bog. "provided it admitted a man to walk over it." (*Essai sur la route*, p. 1819.) The Somersetshire road is so extremely soft, he says, "that when you ride in a carriage along the road, you see the water tremble in the ditches on each side and after there has been a slight frost, the vibration of the water from the carriage on the road will be so great as to break the young ice. I never use large stones on the bottom of a road; I would not put a large stone in any part of it, nor faggots, nor any material larger than will weigh six ounces. If a road be made smooth and solid, it will be one mass, and the effect of the substratum, whether clay or sand, can never be felt in effect by carriages going over the road; because a road well made unites itself in a body like a piece of timber or a board."

3632. *An instructive proof of the preference given by M. Adam to a soft base is derived from a case which occurred near Montrose.* This case was sent to him by Paterson in the following report:—"This road," says the reporter, "for about a mile, goes over a bank of sea-beach, many feet in depth, and all round stones from two to five or six inches in diameter. Always as the stones above three inches work up, and make their appearance on the surface, they are taken off to the side of the road, and broken to the ordinary use. This has been done several times every year for many years back, but the road always continues loose and open as ever." The answer of M. Adam was,—"The road you have sent me a report of is novel in its situation, but very far from hopeless. The sea-beach of which it is wholly composed, should be picked—that is to say the large-sized pebbles should be carefully removed from the surface, and carried to the side of the road, and there broken, not to what your surveyor calls my size, which is six ounces, but smaller say to three or four ounces. And I must also warn you, that any round stone, when broken in half so as to form a hemisphere, is nearly as unmanageable, and as little likely to consolidate in a road, as one left quite round—therefore, with regard to weight, your stones must be taken so as to form as many angles as possible. No large pebble must be left in sight upon the bottom of the road, otherwise they will work up through the broken stones of which your road will be composed—but having prepared a surface upon which to place your road, by removing the large-sized pebbles (I mean all above six ounces), and evenly covering the surface with sand soil or other soft matter, lay on your properly broken stones." Paterson entirely concurs with M. Adam in regard to the advantage of a soft base, adding, in his last publication (*Letters*, &c. 1822), although the ground under the materials can never be too dry, the materials never unite so firmly when placed upon a hard rock or upon gravel, as they do upon earth, moss, or sand. There should always, therefore, be a few inches of the one or the other of these put under the road, as a bed for the materials, where it is on a rocky or gravelly bottom."

3633. *When the base consists partly of firm, and partly of loose, materials, or moved earth, some nicety is required to determine the allowance for the sinking of the latter and, indeed, roads, under such circumstances, cannot often be finished out of hand. Some judicious directions on this subject are given by Paterson.* "When a road," he observes, "is formed along the side of a hill or sloping bank, the earth that is produced from the side-cutting makes up a part of the breadth of the road so that the road is formed, partly on the solid ground, and partly on the embankment. All new made-up earths or embankments subside a little, whatever be the nature or quality of the stuff of which they are composed—for which reason that part of the breadth of the road, that is formed upon the embankment, should be raised a little higher than the solid ground. No precise rule can be given to ascertain exactly how much the different kinds of earths, clays, gravel, &c. will subside—but the following has been found so near to the truth, in most cases, that it may with safety be admitted as a general rule. At all places where there are embankments, whether over hollow ground, or along the side of a sloping bank, for every foot that these embankments or mounds are raised in height, one inch may be allowed for subsiding. So that if an embankment, or the outer edge of a road formed from the side-cutting, requires, for instance, six feet deep of forced earth to bring it to the level required, in that case it should be made six inches higher—namely six feet six inches upon the newly made up ground—and it will be found, in general to be about six months, from the time that the embankment has been made, until it has become properly consolidated."

3634. *Where the bottom is naturally wet and spongy, Stevenson observes, it is well to ram it with chips of stone, or with rubbish somewhat freed from earthy particles. It is extremely desirable, in every situation, that the road-metal should be broken to a uniform size, so as to form a compact body throughout. But, as the preparation of the small metal suitable for the surface of a road is expensive, it will, in many situations, be found advisable to lay a stratum or course of hand-laid stones, of from five to seven inches in depth, with their broadest ends placed downwards, and the whole built compactly together, upon the prepared bed or soil.*

3635. *The materials of the road may be considered in regard to their nature or kind, the proper size and weight, the outline of their upper surface, and the mode of laying them on and consolidating them.*

3636. *Stone* is universally allowed to be the best kind of material for roads; and granite, trap, or flint, the best species of stone next in order are some sorts of limestone, and hard sandstone. Soft claystone is the worst. Limestone is the principal material in Wiltshire, Somersetshire, Gloucestershire, and Ireland; granite and trap in the north of England and Scotland; slatestone in North Wales sandstone pebbles in Shropshire and Staffordshire; flint in Essex, Sussex, and part of Kent and gravel in Middlesex and Surrey. "The stones used for the metals of any road," Paterson observes, "should always be the hardest and most durable that the place or neighbourhood can afford. But this durability will be found in a great measure to depend on the dryness of the road. Freestone, of a moderate hardness, such as mineralogists would term No. 6., 'that would with difficulty yield to the knife, will make a very good road on a dry sloping bank, exposed to the sun and air, or even on a level surface that has a dry gravelly bottom. Nay, even seven or eight inches deep of such metals, on such situations, will make a better road than twelve inches of the best metals where the bottom is constantly damp, and will actually surpass them in point of durability. This, however, is not meant to give a preference to those metals, but merely to show the great difference there is betwixt a wet and a dry bottom, and that such metals will answer very well in the situations above described. Still it must be held as a general rule, to take the best and hardest metals the neighbourhood can afford, as formerly mentioned."

3637. *But the hardest metals will not always be found the most durable; and here it may be remarked, as another general rule, with some exceptions, that the harder they are to break, the greater their durability. Some stones, for instance, as hard as No. 9. of mineralogists, such as would give a few feeble sparks with steel," are so free that they will fly under the stroke of a hammer like so many pieces of glass. These, although very hard, being of a quality so free and brittle, will grind down by the wheels rather easily and in time of rains will be formed into mud while, on the other hand, there are stones not harder than No. 7. that are so tough, that there is great difficulty in breaking them. Yet these latter although two degrees softer, will absolutely last longer than the former, on any road whatever.*

3638. *Flints reduced to a small size, and mixed with chalk, make an excellent road in dry weather but chalk being very absorbent of water, they become slippery and soft in moist weather and are much affected by frost.*

3639. *Whinstone, M. Adam and all road engineers agree in considering the most durable of all materials and, wherever it is well and judiciously applied, the roads are comparatively good and cheap. Fry, however has uniformly observed, in various parts of England, that where limestone is used, the roads are the best and this superiority is not in his opinion owing merely to the hardness of this substance, but also to its adhesion or cementing property. how otherwise, he says, are we to account for the firmness and solidity of the road around Bristol that are made of white limestone. Fall mentions dewstone, which abounds in Nottinghamshire and other counties of the North, as equally durable with whinstone. (Every Man his own Road-maker p. 8.)*

3640. *Gravel is of two kinds that obtained from pits, and that from the beds of rivers. Gravel is generally silicious and hard otherwise, indeed, it would have been worn down to sand in undergoing the operation with has rendered it gravel. This material is chiefly used on the roads round London it is often found, Paterson observes "to answer very well in point of durability. But such kind of gravel being composed chiefly of hard sand, and smooth, little, round stones, does not so easily bind together and seldom makes a very firm road. On the other hand, stones that are broken have so many sides that they readily lock into one another whereas the small round gravel keeps rolling and shifting about by every motion of the wheels. All road metals, therefore should be of stones as large as to require breaking before they are used. The roads on which gravel will be found to answer best, are those which are neither too wet nor too dry. I have seen a road made with such materials, not only easily rutted in time of the winter rains, but the same road, in the drought of summer, became as loose as ashes, and was then also, very easily rutted while betwixt these extremes it answered exceedingly well. Upon the whole, it would be improper to use gravel for any turnpike or public road, where stones can be got that require to come under the hammer. (Treatise, &c. p. 31.)*

3641. *The gravel of which roads are usually formed is mixed with a large portion of clay and the component parts of gravel are round, and want the angular points of contact by which broken stones unite and form a solid body the loose state of the roads near London is a consequence of this quality in the material, and of the entire neglect or ignorance of the method of amending it.*

3642. *Gravel is the worst material for making roads subject to great traffic. Telford, on being asked his opinion of it by the road committee, replied, "I am of opinion that the materials in the whole valley or plain round London being entirely silicious, or flint, and easily ground to dust, are very improper. This must be evident to every person who travels near London in any direction." In this opinion M. Adam concurs.*

3643. Artificial materials for roads are sometimes had recourse to, when stone or gravel is not to be procured, and sometimes used because unfit for any thing else. They are chiefly the scoria of founderies, dross, cinders, &c. to which may be added burnt clay; the last a very perishable material. It is burned in clamps like bricks, and differs from them in being in irregular masses, and in not having been previously worked.

3644. Chambers's substitute for road metal, or for gravel in gardening, is nothing more than vitrified clay, loam, mud, or any other earth that will not fall to powder or burn to lime. The material is intended to be burnt in a temporary kiln, to be erected by the side of the road about to be made or repaired; the earth may be taken from the side drains. The kiln are to be of about six yards in width, and of any length. A stratum of dried earth is to be laid about two feet in thickness, between two layers of combustible, so as to turn to a vitrified state the greater portion of the earth so enclosed. The principal part of the contents of the kiln will then be in lumps which are to be separated from the dust or powder, and such vegetable matter as produces alkali may be burnt with the other materials to assist the vitrification. Salt, brimstone, potash, or soap-ashes also if they can be procured at a small expense, may be employed for the same purpose. The dust unavoidably produced or remaining from the above described burning of clay, &c. having been separated from the vitrified matter is first employed to damp or extinguish the fire and afterwards, though not applicable to road-making, becomes a valuable material, and may be appropriated for dressing land. (*Newton's Journal*, vol. 1. p. 354.)

3645. The preparation of materials relates chiefly to their proper use or weight, and cleaning from earthy matters.

3646. Breaking the materials evenly is a point, Marshal observes, on which very much depends for by doing this, the wear of the road becomes regular. Where the heads of large stones rise above the general surface, they become obstacles to carriages, and stumbling-blocks to horses beside their tending, by the jolting motion which they give to carriages, to indent the surface on either side of them and thus to increase the roughness, and hasten the decay of the road.

3647. The proper size of road stones requires much latitude. Not only the intended use of the road, but the nature of the material, is to be considered. A road for broad-wheeled carriages of burthen only may be made of larger stones than one for narrow wheels and hard stones require to be broken smaller than those which more readily wear down and form a travelable surface. For when once the surface of the materials becomes united and cemented together and its rock-like texture established, the stones that are crushed, and the smaller fragments which are splintered off, in wear serve to encrust and bind together the stratum of stones which lie next in succession beneath. especially if proper attention be paid to the irregularities of wear and to bring back the surface, wherever it is requisite, to its original evenness of convexity so that it may in every part, act as an arch, and may be able to resist, with the greatest firmness, the weight with which it may be impressed.

3648. In forming and repairing roads with stones of large size, a considerable share of the expense arises from the labour of reducing the materials and, in consequence the smaller they are broken, the greater becomes the expense. This, on ordinary occasions, is a serious consideration. Hence, in constructing and repairing common roads, it is advisable, — instead of reducing the surface stones to small fragments, with the hammer at a great cost, — to cover them with materials that are already reduced as the rubbish of stone quarries, soft stones or gravel, or the scrapings of the road to be repaired. Such cementing materials being washed and worked down, by rains, and the action of carriages and the feet of travelling animals, among the surface stones, assist much in binding and fixing them in a firm crust, and in making the road immediately passable by horses and light carriages most particularly if the whole be compressed and united together, by a heavy roller (suitable to the purpose) repeatedly passed over the surface. Such is Marshal's opinion how much it differs from M<sup>r</sup> Adam's and Paterson's cannot but be remarked by the reader.

3649. The size of stones preferred by Edgeworth is not specifically mentioned but on page he would lay stones of six or seven pounds weight he elsewhere observes that no stones larger than an inch and a half in diameter should be left on the surface of the road.

3650. The size which Walker approves of he has not given in very definite terms and his observation as to the foundation acting by an arch is, in our opinion, erroneous. He says, "Where whin or other stone is to be used, the size of the pieces into which it is broken should decrease as we approach the surface — the superficial coating not exceeding a cube from one inch to one inch and a half. If the foundation is bad, breaking the bottom stone into small pieces is expensive and injurious, upon the principle I have above described, and also for the same reason that an arch formed of whole bricks, or of deep stones, is to be preferred to one of the same materials broken into smaller pieces for in some counties the materials will admit of the foundation of the road being considered as of the nature of a flat arch, as well as of being supported by the strata directly under it."

3651. The size of metal, according to Paterson, should be different for the upper and under surfaces of roads and both should be regulated according to the situation of the road, and the nature of the ground over which it is formed. "Such small broken

metals as are most proper for a road formed on a sloping bank, or on a very dry bottom, would be quite improper for a road that is perfectly level, and is much subjected to dampness. In the former case, even six or eight inches deep of such metals will make a good road but in the latter case, twelve or fourteen inches will be found inadequate. In the former case, too, the metals should be of such a size as may fill and pass through a ring from two to two inches and a half in diameter and in the latter case, they should not be under three inches as under that size I have never found them to make a durable road in such situations. Every road that has more than eight inches deep of metals, should have the half of these in the bottom broken considerably larger than those on the top. If the road, however, has a dry hard bottom there is not so much need for this; but if the bottom is soft and wet, it is of the greatest service in making a firm road, and preventing the metals from sinking and the softer the bottom, the larger of course, they should be. But it is to be remarked, that the same author in his *Lettres*, &c. published three years afterwards, says, In my former treatise I proposed, where the bottom was soft, to have the under course of stones a little larger than those at top. This I have seen of service, in several cases but my mode of draining, which should never be neglected, supercedes this entirely.

3652. The criterion of size adopted by M<sup>r</sup>. Adam is six ounces, or under, for every part of the stratum.

3653. The size approved of by Clarke is not defined, but it should he says, be small. "The common practice is to lay a stratum of stones nearly the size of a man's head, as a foundation and to cover them with two or three inches of smaller ones but, from experience and observation I am decidedly of opinion, that all the stones should be small and as nearly as possible of the same size for, though a road made as above described may be very good at first, the wheels of carriages will grind the small stones to powder the large ones will then rise to the surface, and the road will become intolerably rough, and though frequently repaired with new materials, the same cause will produce a similar effect whereas, if all the stones are small, and nearly of the same size, they will soon be cemented into one solid mass, and will be worn evenly to the last, so that no repairs will ever be necessary but the addition of a few broken stones occasionally (*Obs. on Roads* p. 11)

3654. In fixing upon the size of the top metal, Stevenson observes, 'the more hard and tough its nature is, the smaller it may be broken it being an object of main importance to have the metal well assembled as the road-makers express it, or broken of a uniform size. In almost every county there is a variation in the quality of the rock, and also in the size to which it is broken. Roads have lately been made under a specification as to the weight of the pieces varying from six to eight ounces. Formerly it was not uncommon to have them specified, of the size of a 'hen's egg, or even of a man's fist. By reference to weight, the road-maker's operations became more precise but regard should also be had to the specific gravity of the materials, which differs considerably. For example granite may be taken at twelve cubic feet in the ton, and whinstone (the greenstone basalt, and clinkstone of mineralogists) is often met with of similar weight. Compact limestone and flint are about fourteen and quartz sandstone about fifteen feet to the ton. Perhaps the most convenient and uniform test for the size of road metal is a ring measuring two inches and a half diameter in the void. When the metal is thus broken, and the road carefully treated, its surface soon becomes smooth and compact, without requiring the addition of blinding or filling up the interstices with gravel, which if used, should be free of earthy particles. But this addition is hardly necessary where there is much traffic, as the rough and angular sides of the metal soon lock into each other and form a smooth surface.' (*Ed. Encyc. art. Roads*.)

3655. The mode of preparing gravel is nearly the same by all the best road engineers, who agree with Telford, that it ought to be completely cleansed of every particle of clay or earthy substance, and its different sizes ought to be selected and arranged by means of riddling or washing. In the use of the riddle the particles of earth or clay adhere so much to the stones, that it frequently requires to be exposed to the sun air and frost, for several months, and then riddled over again. In this gravel the stones are of different sizes and different shapes all those that are round ought to be broken with a small hammer. Some attempt to attain the same end sooner by washing; but this is both a more expensive and less effectual mode than that of taking advantage of the weather.

3656. The mode of breaking stones recommended by Edgeworth, is by persons sitting, and using small hammers. A hard stone should be used as an anvil, and the stone to be broken may be advantageously held in a forked stick. Attempts were made some years ago to break limestone for roads, by the force of horses, wind, and water. Stampers, shod with iron, and raised by proper mill-work, were employed they were let fall upon blocks of whinstone. These mills were found profitable for breaking limestone to powder as a manure, where fuel was scarce but they crushed the stone to dust rather than to fragments if lighter stampers were employed, they frequently failed to break

the stone. Feeding the mill was also found difficult and dangerous. This unsuccessful attempt should not discourage mechanists from further trials. Stones previously broken to the size of five or six inches, might be thrown upon a strong circular horizontal grating, made of cast iron. The stones might be forced downwards through this grating by an iron rammer or a sledge they would thus be broken to fragments that could not exceed a certain size, and that would not be reduced to powder.

3657. *The manner of breaking, according to Telford, is of great importance.* More depends, he says, on the weight, shape, and manner of using hammers, than any one can conceive who has not had much experience in road-making the difference in managing this operation being not less than ten per cent. and is, besides, of equal importance towards the perfection of the road. The size and weight of the hammer he would apportion to the size and weight of the stones and the stones should be broken upon the heap, not on the ground. It must be evident that using round stones, instead of broken ones, will be the means of deranging the position of those near them, and of grinding them to pieces.

3658. *According to M<sup>r</sup> Adam, the only method of breaking stones, both for effect and economy, is by persons sitting* the stones are to be placed in small heaps and women,

541

boys, or old men past hard labour, must sit down with small hammers and break them, so as none shall exceed six ounces in weight.

3659. *In Nottinghamshire, and part of Yorkshire, a very convenient portable machine is employed for the breaking of small land and waterworn stones. The diameter of the stones to be broken according to the mode in question should not exceed five or six inches they are placed on a table of a triangular shape (fig 541), boarded on three sides like a dressing-table, but open at the narrow end, which is placed next and in front of the operator, who sits on a stool (b) or stands as he may*

choose, and has a block between him and the point of the table (a), the top of which is about six inches lower than the top of the table. By means of an iron ring fixed into a handle of wood (fig 542), he draws from the table as many of the stones as the ring will enclose on the block, and then breaks them while still enclosed in the ring, which is held by his left hand. When this is done, then, with another motion of his left hand, he draws them in the ring off the block till they form a heap at one side, or he at once drops them into the hand-barrow measure (fig 543.) To prevent any fragments from getting to his face, he puts on a wire guard or veil (fig. 544.) which may be tied by a ribbon round his head, or

542

543

suspended from his hat. The same hand-barrow which serves as a cubic yard measure,

serves to carry the stones to any distance. The price paid is so much a yard. In some places, the breaking apparatus consists of three separate parts, the table, the block, and the stool in others, the whole is combined in one machine, furnished with a wheel (fig 541 c), which serves as one foot when the machine is stationary and handles (d); and which admits of moving it from place to place, as easy as a common wheelbarrow. All that is wanted to render this apparatus complete, is a portable shelter or shed, which might be formed entirely of plate-iron, to move on three wheels, or a slight iron frame on three wheels, to be covered with reed frames or straw matting. The shelter should be formed so as not only to protect from perpendicular rain or sun, but from side winds and drifting snows or mists. (*Gard. Mag.* vol. v)

544

3660. *Boulder stones, according to Fall, "are broken with a hammer upon a block made of cast iron. The hammer should weigh about three pounds and a half or four pounds, with two flat faces of about an inch and a quarter in diameter, and a handle similar to a blacksmith's hammer. The cast-iron block must be six or seven inches square, and three inches and a half in thickness, and let into a piece of coarse solid wood, about thirteen or fourteen inches square, and seven or eight inches thick. The block, when used, is to be placed firmly upon the ground, with a kind of trough so fixed that the*

pebbles may, with ease, be brought on the block with a ring. The ring should be about five or six inches in diameter, an inch and a half in breadth, and a little thicker than hoop-iron, with a short handle so it this instrument is used for confining the stones on the block, while going through their operation. The trough has four feet to support it, two of which (those nearest to the breakers) are no longer than what is necessary to allow the stones to come upon the block the other two are placed at a little distance from the block, and should be somewhat longer, in order that the far end of the trough may be higher, say four or five inches by which means the person who breaks the stones will, with ease, pull them up on the block; and, as he must always be in a sitting posture, it is requisite that he should get all the advantage over them he can. The trough is, in form, like a washing tub, except that the end next the block is much narrower than the other, and left open, at the bottom of it—the end next the block—should be fixed a grate, to let through the dirt or sand which is shovelled up with them when put into the trough. It will sometimes be of great advantage to gravel, when clay earth, or other matter adheres to it for by constantly removing it about, and being frequently exposed to frost, wet and dry weather, the dirt becomes tender and moulders into pieces, which the grate will readily separate, without any hindrance to the breaker or waste in the stone. A blacksmith's anvil is the best block and a box or trough, made as just described, must be framed so as to agree with it. (*Fulk's Surveyor's Guide*.)

3661. *Breaking by machinery.* On a new line of road, between Bury and Bolton, in Lancashire, a rotatory steam-engine is attached to a machine similar to a stone-mill, but considerably stronger, which breaks the stones to cover the road at the astonishing rate of seventy or eighty tons in ten hours. The engine is movable on wheels, so that it can be removed to any part of the road without being taken to pieces. (*London Journal of the Arts* &c. Sept. 1822.)

3662. *M. Adam's criterion for size is weight.* On being asked by the road commissioners to mention the dimensions he stated, that there was very little difference in the weight of the stones used in road making. "I did imagine," he says, "that a difference existed but having weighed six ounces of different substances, I am confident there is little difference in appearance and none in effect. I think that none ought to exceed six ounces. I hold six ounces to be the maximum size. If you made the road of all six-ounce stones, it would be a rough road but it is impossible but that the greater part of the stones must be made under that size."—"Do you find a measure or ring through which the stones will pass, a good method of regulating their size?"—"That is a very good way but I always make my surveyors carry a pair of scales and a six-ounce weight in their pocket, and when they come to a heap of stones, they weigh one or two of the largest, and if they are reasonably about the weight, they will do it is impossible to make them come exactly to it."

3663. *With respect to the size of stones,* Paterson disapproves of six ounces being made the maximum, as proposed by M. Adam. "I find," says he, "there are many under the weight that are yet of a very improper shape and size even from three to four inches between the extreme points. Besides, scales for weighing are not so portable nor convenient as gauging-rings for the size. The ring I generally use is two inches and a half in diameter, and the stones should be broken so that the largest may pass, in any direction, through it. On this plan you have the materials smaller more equal, and more square in shape, than on his plan. An inexperienced person, on the first view of it, may think otherwise; but it is a fact, that taking my ring as a gauge, you will not have five stones in a thousand that will exceed four ounces in weight, and none of improper shape or dimensions while on Mr M. Adam's plan you will have more than twenty in a thousand that will not pass longitudinally even through a three-inch ring. It is now nearly three years since I first heard of his standard weight. During that time I have had people both working to it, and also to my ring gauge but I have uniformly found that mine are so much smaller, that they cost about a fifth more in breaking than his. Upon the whole, then, I would recommend the ring as every way preferable to the scales and I have no doubt that it would be an improvement even to reduce the ring a little, where the ground under the road is completely dried by the method I have described."

3664. *With respect to the depth of metals,* Marshal mentions twelve inches: but Edgeworth considers an average of nine inches as sufficient for any road on a good basis and two thirds of the quantity he says, will make an excellent road at a distance from any great town.

3665. *The depth of materials, according to Walker* depends so much upon the soil and the nature of the materials themselves, that it is impossible to lay down any general rules for them. The thickness ought to be such that the greatest weight will not affect more than the surface of the shell and it is for this purpose chiefly, that thickness is required, in order to spread the weight which comes upon a small part only of the road over a large portion of the foundation.

3666. *The depth of solid materials recommended by M'Adam is one of ten inches, which he thinks equal to carry any thing when well consolidated, and whether on a soft or hard substratum, he should prefer a soft one. (Examinations, p. 1819)*

3667. *The depth of metals, according to Paterson, should be regulated according to their quality, the situation of the road, and the nature of its base. On the generality of turnpike roads it should be made from ten to twelve inches and upheld afterwards at the depth of nine or ten inches. Yet, in some situations, even six or eight inches will make a much better road than twelve or fourteen in other situations.*

3668. *The depth, according to Stevenson, must depend a good deal on the quality of the rock, but it should seldom be less than eight inches in all those parts of the road on which carriage wheels may be supposed to pass. Towards the verge, it may be less (Ed. Encyc. art. Roads)*

3669. *With respect to the shape of the surface of the metals, almost all road-makers agree that it should be convex, but they differ a little in the degree of convexity. It is also allowed by most of them that on roads up ascents, the surface of the metals may be flat, bevelled, or somewhat inclined to one side. Concave roads are not here taken into account, as they require a different general plan and may be considered as not resorted to in preference, but from accidental circumstances.*

3670. *Concave roads (fig 545) were recommended, and to a certain extent adopted, by the celebrated Bakewell of Dursley. Practically considered, such a road is in effect nothing more than a flat road with a gutter in the middle, instead of a gutter at each side.*

545

3671. *The proper convexity of a wet-weather road, according to Marshal, is to be regulated by a variety of circumstances, as, first, by the materials of which it is to be formed. Soft materials are most liable to be worn into ruts and hollows, and require to be laid up with a quicker descent for rain-water than hard materials, which require less elevation or rotundity of surface and least of all a firm even pavement. Secondly, a convex road in the face of a steep is to be laid up higher with a given material, than one on more level ground, on which rain-water has no other tendency than to the sides; whereas, in the face of a steep it may have an equal or greater tendency along the line of the road, and is liable to be caught by the slightest impressions of wheels and thus to wear channels, as may too often be seen, from the top to the bottom of the hill. Even where the surface of the road is perfectly smooth, it may have twice the distance to run, before it reaches the outer margin, that it has on a level. And, thirdly, the degree of convexity is to be determined, in part, by the width of the road the materials and descent being equal. A wide road requires to be formed with a greater sideways descent than a narrower one which more readily frees itself from rain-water, inasmuch as the distance is shorter from the crown to the outskirts of the road. Nor is freeing a road from rain-water the only object to be kept in view with regard to its convexity. The ease and safety of carriages, and particularly those of burthen, whose loads, being of light materials, are laid up high, require to be consulted. A carriage moves most freely and with the least exertion of draught, when the load lies evenly upon the wheels on each side. In proportion as the weight is thrown on one side, or the other the resistance is increased especially on a road which is liable to impression. Hence an inconvenience of a highly convex road in the face of a steep, and hence the utility of breaks in long ascents.*

3672. *It is evident that every part of a road should be equally and duly convex — should be equally safe and easy for carriages of every description, — otherwise it becomes more partially worn the more level parts only are used, the steeper being in a degree useless. Hence a road of even and due convexity is not only easy and safe, but may be formed of a narrower width, than one whose steep sides are neither easy nor safe to be travelled, and whose crown only is in use. On measuring different passages of roads which appeared to be in the most desirable form, Marshal found that their convexity or the elevation of the crown or middle of the road above the base line, in roads of twenty feet in width, was about ten inches, namely one inch in every foot on each side and he is of opinion that this result may be taken as a general guide in forming roads the middle degree of convexity being liable to be altered, according to the width of the road, the nature of the materials, and other circumstances.*

3673. *A whole barrel or concave road cannot easily be kept up in a narrow lane, as in the case of narrow lanes. If raised, it presently wears into a middle track and two wheel-ruts, with foul drains on each side of them, and becomes, in wet weather, a dirty trough, which is unfit for either carriages or horses, and in which a foot passenger has not where to set his foot. But if such a lane be thrown into a shelving form, resembling*

half a barrelled or convex road, a greater width of travelable road for carriages and horses will be obtained; ruts will not be so liable to be formed; the whole of the water of rains will be thrown to one side, while the other will afford a comfortable walking path, at all seasons. It is to be remarked, that when water in a wet season is apt to come out of the banks on the upper side of the lane, a narrow channel is to be cut, to prevent its overflowing the road, or in forming the bed of the road, the inclination may in some cases be reversed, so as to throw the drain on that side of the lane whence the spring water issues: thus the same drain will serve for the spring and the rain waters.

3674. *Semi-convex roads* are applicable not only to narrow lanes, but to the sides of hills, where the road, as it generally ought, is conducted sidelong (not directly) up the slope. By this form of the road, the whole of the water which falls upon it will be got rid of without inconvenience or expense; and the bed of the road for this purpose may be made narrower than for a full convex road, — a circumstance which in some cases may become a saving of much expense. The upper side of a road in this form being nearly level, and firm to the foot of the steep, would be chosen by ascending carriages, while the lower side would acquire a looseness of surface, and be used by laden carriages going downward; while a raised footpath on the lower margin would be a secure guard, and a relief to the apprehensions of timorous travellers.

3675. *The convexity of a road, according to Edgeworth*, need be no more than what will prevent it from being worn hollow before it can be conveniently repaired and he very judiciously assigns as a reason, that no lateral inclination of the ground, consistent with the safety of carriages, would empty a rut of three inches deep. So far from this being the case, whoever attends to the fact will find, that, even down a moderate slope, where any dirt remains upon the road the water will be obstructed. Even if there are no ruts on a road, the mud and sludge will not run down a slope even of two degrees, which is the utmost inclination that should be permitted on a mail-coach road.

3676. *The degree of convexity preferred by Benjamin and John Furry* is one of twelve inches in a road fifty five feet wide but to attain this shape when the road is worn down, in first forming there should be a rise in the centre of sixteen or eighteen inches.

3677. *The convexity preferred by Telford* is no more than is just sufficient to permit the water to pass from the centre towards the sides of the road the declivity may increase towards the sides, and the general section form a very flat ellipse, so that the side should (upon a road of about thirty feet in width) be nine inches below the surface in the middle.

3678. *The degree of convexity proposed by Clarke* a young Irish road-surveyor is still less than that of Telford. Were it not absolutely necessary, he says, to let the rain-water run off quickly the best shape for a road would be a flat surface, and, therefore, the nearer we can approach to that form the better for if the road is much elevated in the centre, wheel carriages will all run in the middle and, of course, very soon wear that part into deep ruts and if they are then forced to go upon the sides, almost the whole weight will press upon the lower wheel, which will, of course, sink deeper and occasion a distressing resistance to the shoulder of the horse at that side therefore, as before observed, the flatter a road can be made, consistently with a moderate fall for the rain-water to escape, the more convenient and durable it will be for a road should be as hard and as smooth as possible. An idea of a perfect road may be formed from a frozen canal, where fitness, smoothness, and hardness, are combined in imitation of such a surface railways were invented, and fully illustrate the principles assumed. Roads cannot be made so as fully to attain those perfections but we should always have them in our view for the nearer we approach to such a standard, the less will be the friction, and the greater the facility of draught. On a site of sixty-three feet he forms a metalled road of thirty-four feet, with a rise of nine inches in the middle a six-foot path at one side and a ditch and bank at each side, occupying ten feet six inches. (fig 546)

3679. *The degree of convexity preferred by Walker* is just a sufficient rise towards the middle, to incline the water to the sides and in place of making the whole width the section of one curve, to form it by two straight lines, forming inclined planes, and joined by a curve towards the middle. "I have seen," he says, "ridges formed in what I

straight well-defined land, much after what I would recommend for the form of a road. The object of forming the land into ridges, raised a little in the middle, is the same as that of raising the middle of a road, to prevent the water from settling upon it, and what is sufficient for the ploughed land, is certainly enough for a road. If the road is of good stone, four to five inches rise in ten feet is sufficient; gravel and other inferior material will allow a little more. This shape not only enables the water to pass from the centre towards the sides, but greatly contributes to the drying of the road, by allowing the action of the sun and air to produce a great degree of evaporation. Surveyors ought to use a level in giving roads a proper shape, in order that the surface may be of one uniform curvature, without the smallest deviation, in any one spot, from the prescribed line of the cross section."

3680. *The degree of convexity preferred by Mr. Adam is less than that approved of by any of the road-engineers mentioned, unless perhaps Edgeworth.* "I consider" he says, "that a road should be as flat as possible, without regard to allowing the water to run off at all, because a carriage ought to stand upright in travelling as much as possible. I have generally made roads three inches higher in the centre than I have at the sides, when they are eighteen feet wide. If the road be smooth and well made, the water will run off very easily in such a slope. When a road is made flat, people will not follow the middle of it as they do when it is made extremely convex, which is the only place where a carriage can run upright, by which means three furrows are made by the horses and the wheels, and the water continually stands there, and I think that more water actually stands upon a very convex road, than one which is reasonably flat."

3681. *If a road be high and convex in the middle,* Fry observes, no care of the surveyor can prevent the formation of a pair of ruts along the ridge of the road from an instinctive operation of fear every driver will take this track, as being the only part of the road where his carriage can stand upright and even if it be not so convex as to excite fear, yet the inconvenience of travelling on a sloping road will always produce the same effect.

3682. *The convexity recommended by Paterson on the level ground, where the bottom is dry should be from one inch to one inch and a half in the yard.* From this, the declivity may increase even to three inches in the yard just in proportion as the ground increases in wetness but beyond that declivity it would probably be improper to carry it in any instance. If the bottom, however is dry sand or gravel, the convexity should be very little indeed. But in all cases, whether wet or dry, a road formed on sloping ground, should be very nearly level from side to side. The reasons are obvious. In the first place, it is well known that carriages running quickly over a hill, are more easily overturned than on level ground it would therefore be dangerous, in this respect alone, were the road to have much slope on the sides. In the next place as the great end in giving it the convex shape is to run off the water and prevent it from lodging this is not so necessary on a road formed upon sloping ground, as there the water will not lodge so as to injure it. In his second work (*Letters, &c.*) Paterson observes of the above directions, "In my treatise respecting the form of the road I proposed the slope from the edges of the materials, to the side ditches, to be from an inch to an inch and a half in the yard, where dry; and to increase the slope a little, where wet. But by adopting these drains under the road, no greater slope will be required, in any situation, than an inch to the yard."

3683. *The convexity recommended by Stevenson is, where the road passes through a level track of country, an ellipsis, "falling from the centre to the verges on either side, at a rate not exceeding an inch and a half perpendicular to a yard horizontal. (fig. 547.)* But

when an acclivity in the line of draught occurs, where carriages are in the greatest danger of being upset, the surface of the road should be kept flat, or with a fall not exceeding three quarters of an inch to the yard, so take the water gently off toward the sides, and prevent it, during heavy rains, from rutting the road in a lateral direction." (*Ed. Engrs. art. Roads.*)

3684. *With respect to the order and mode of laying out the materials there is some difference of opinion.* Some begin with the largest, and finish with the very smallest, or with gravel; some lay on the whole at once, and others in two or more strata, and so on. That such a mode of depositing materials could never make a good road is evident, for the reasons given by Mr. Adam and Clarke: the larger stones would soon rise to the surface, and roll about loose on it the strata, being thus broken up, would admit and

retain water, which, by the traffic of the road, would render the substratum, in all such places, a mass of mud; and the whole would become bad in proportion to the traffic, the subsoil, and the climate. Marshal is equally wrong in his directions for forming farm-roads, by filling the wheel-tracks with hard materials. In depositing these, he says, the largest and roughest are to be thrown to the bottoms of the wheel-tranches, as foundations for the hardest, which ought to receive the immediate pressure of the wheels, the softest and finest being disposed of in the horse-track. It is evident the continual action of the wheels in the same rut, aided by the water which must infallibly lodge there, would soon work up the larger and rougher stones, and render the traction more oppressive than if no metals had ever been laid there.

3685. *Telford's mode of disposing of the materials of roads is as follows* — Where a road has no solid and dry foundation, it must be constructed anew. Upon the eighteen centre feet of it stones must be put, forming a layer seven inches deep. Soft stones will answer, or cinders, particularly where sand is prevalent. These bottoming stones must be carefully set by hand, with the broadest end down, in the form of a close nest pavement the cavities should be filled with stone chips, to make all level and firm, and no stone should be more than five inches broad on its face. Over its bottoming of stones or cinders, six inches of stones, of a proper quality, broken of a size that will, in their largest dimensions, pass through a ring of two and a half inches diameter, must be laid. The six feet of the road, on each side of the eighteen centre feet (making thirty feet), when formed of a proper shape, may be covered with six inches of good clean gravel, or small stone chips.

3686. *No covering or mixture of any sort is added to the material by Edgeworth, except clean angular gravel that may insert itself between the interstices of the stones; but no more should be used than what will thus sink to a level with the surface.* If the whole were covered with gravel, it would be impossible to discover the defects of the road, till it might be too late. No stones larger than an inch and a half in diameter should be suffered to remain on the road where much inaccuracy in this respect is suspected, an iron ring may be employed as a gauge. In all cases, after the road has been covered with stones, it should be carefully examined, and every stone that is too large should be picked off to be broken smaller.

3687. *The preference generally given to gravel, Paterson considers to be greater than it deserves, and that the earth obtained from the sides of the road, free of expense, will not only barely answer the purpose, but in most cases equally well and that on a perfectly dry bottom it is questionable whether it should not even be preferred to gravel.* It is in winter only, and on wet ground, that I consider gravel entitled to any preference whatever. (*Treatise, &c. p. 45.*)

3688. *The mode of laying on gravel according to Walker, 'is to lay it on as it comes from the pit, except the upper foot, or eighteen inches or so, which is screened but in all cases, whether the material is gravel or hard stone, the interstices between the pieces should be filled up solid with smaller pieces, and the finishing made by a thin covering of very small pieces, or road-sand or rubbish for those interstices must be filled up before the road becomes solid, either in this way or by a portion of the materials of the road being ground down, which last mode occasions a waste of the material, and keeps the road unnecessarily heavy and loose.* In the original making or effectually repairing of a road, it is, I think, best that the whole of the proposed thickness be laid on at once, for the sake of the road as well as of the traveller the materials of the road then form a more solid compact mass than when they are laid in thin strata at different times, for the same reason that a deep arch of uniform materials is preferable to a number of separate rings." Laying on a stratum of unsifted gravel, under a sifted stratum, is rather at variance with the doctrine of "a deep arch of uniform materials," and it seems to us, that when a stratum of properly broken stones are to be powerfully rolled, the previous filling up of their interstices with very small matters might counteract the effect of rolling, in squeezing the angular stones into the angular interstices.

3689. *The mode of laying on gravel by M. Adam is that of scattering with a shovel, and never emptying down cart or barrow-loads on the middle of the roadway, as is generally practised. He completes the stratum by three separate layers, leaving the first to be consolidated by wheels, and in some cases a heavy roller before he lays on the second and the second, in like manner before he lays on the last.*

3690. *A covering from four to five inches thick according to Fry, forms a bed or mass, which is proof against the severe crush of heavy wheels; while in the case of a very thin covering, the stones lying bare upon a hard road, and receiving in this unprotected state the strokes of every wheel that passes over them, like the thin covering on a mill-bed, they are quickly reduced to powder, and disappear. Stones in a thick bed are protected from the immediate destructive grind, while stones that are thinly laid on are instantly reduced to powder either by pressure or grinding.*

3681. *Process*, in filling broken stones, and also in scattering them on the road, makes

use of a pronged shovel, fourteen inches square, which may be universally recommended for this purpose (fig. 348 d). His large hammer (e), small one (b), and gauge for the size of the broken stone (c), are in very general use, as well as the pronged shovel. Hammers may be made of cast iron, where the stones to be broken are about their own weight, the best shape is a narrow oval; the advantage of using cast iron is its cheapness. (*Farm. Mag.* xlii. 159.)

3682. *Telford's level* for adjusting the declivity of roads from the middle to the sides (fig. 349.), is also a very complete implement of the kind.

3683. *The mode of depositing materials by Paterson is as follows* — "Bottom metals should be broken on the road. When they are thus broken, they are, by the force of the hammer firmly bedded into the bottom, and are so closely and compactly beaten together, that they become like pavement. In this state they are not only less liable to sink, but they form a much better bed for the top metals than when they are thrown loosely on. And besides this, when they are put on in a loose manner as is frequently done, the mud more readily works up through the metals in time of rains, and makes a disagreeable road: the top metals also are easily beaten down, by the horses' feet and the carriages, through the bottom stones, when loose and open, so that the small metals frequently get undermost, and the large ones make their appearance at the surface, very much to the injury of the road. Taking all these circumstances, therefore, into consideration, it is of the greatest importance that the bottom metals should not only be much larger in size, but that they also be broken on the road." This may be considered as at variance with several parts of Paterson's second publication, *Lectures*, &c. The road being drained and prepared for the materials, he then directs (p. 80.) to put them on in the following manner: — "M'Adam's mode of putting them on, in coats of three or four inches, though good in particular instances, will not do as a universal rule. If the bottom is wet, and the weather rainy the earth will poach and work up through the materials, in spite of all the attention and care that can be bestowed. I would, therefore, recommend in such cases to put on the first course from five to six inches thick. But then to leave these materials to consolidate, or rather to move and shift about by the wheels and then to be levelled by the rakes, alternately, according to M'Adam's plan, wears away the corners of the stones, by which means they do not unite together and make such a firm road. There were upwards of two miles of road made under my directions lately, on which I caused a course of about six inches to be put. But before opening it to the public, I got a heavy stone roller to ply upon it for four days. This beat and firmed the materials so much, that the wheels of the carriages made little impression upon it. Of course the materials retained their angular points more than in rolling and shifting by every carriage-wheel that passed and there was less labour in raking and levelling the road. This plan, which carries reason on the face of it, I would strongly recommend. As to M'Adam's plan of putting on the materials in shovelfuls, it is certainly good. I used to prohibit putting them on with carts (as in that case you never have the small and the great properly mixed together), and generally put them on with wheelbarrows; but even this does not mix them quite so well as scattering them with the shovel; and as it is of considerable importance to have them well mixed, I would by all means recommend the mode best calculated for that purpose."

3684. *Rolling newly laid on metals is generally approved of.* The roller used should not be less than four or five feet in diameter; a smaller size, especially in the use of gravel, being apt to drag and force the loose materials before it. Some have attempted to keep roads in order by occasionally harrowing and then rolling them, but the best

judges are of opinion with John Farey (*Evidence*, p. 1619.), that a roller cannot be beneficially used upon a road at any other times but after new coating it with materials, or after a frost, or when the sticking of materials to the wheels may have loosened up the stratum.

3695. *Beston's new theory of roads*, as given in vol. 1. of the *Communications to the Board of Agriculture*, is as follows — Water percolates through porous strata, and is retained by compact strata. Whatever may be the form of the surface, therefore, if there is a porous stratum underneath, the surface will be generally dry. When a new road is to be formed, reduce the natural surface so as the lines of a section of it may meet in an angle or ridge in the middle of the road (*fig. 350. a*), having a slope from thence of

550

about an inch in a foot. The road being thus formed, must be allowed to harden and settle for some time, and then covered to a level, by a stratum (*b b*) sufficiently porous to admit water to pass through it. Small drains (*c c*) being formed at the sides, to lead the water from the gutters (*d d*) into the open ditches (*e e*). Over this is to be laid the coat of hard materials (*f*) which need not be more than 6 or 7 inches in thickness, of stones broken very small, or of the best gravel. It is then to be rolled with a roller, which admits of being loaded, so as to render the surface harder and harder by degrees. The advantages of this construction, Mr. Beston tells us, are, every part of the road being equally commodious for carriages and very little repair required. These advantages, however, are by no means obvious.

#### SECT. IV. Paved Roads.

3696. *Causeways and pavements* are chiefly made use of in towns, and may therefore be considered as belonging more to architecture than to agriculture. But as it is the opinion of some of the first engineers, that pavements might be introduced with advantage on the public roads for some distance from the larger towns, we shall shortly consider this subject with reference to that object. Paving, as applied to roads, is therefore to be considered as a substitute for a part or the whole of the metalled part of the road, and not as occupying every part of its width or site, as in the case of streets.

3697. *For roads near capital or great commercial towns*, paving according to Edgeworth, is the only certain method yet known that gives sufficient hardness, smoothness, and permanency. B. and J. Farey are of the same opinion, and the latter considers it would be proper to pave the sides of all the principal entrances into London. Walker who was the engineer of the Commercial Road, ten feet of the centre of which is paved with granite, and has given great satisfaction for upwards of 16 years, is a great advocate for paving. "The advantage," he says, "of paving part of a road where the traffic is great, and the materials for making roads bad or expensive, is not confined to improving the conveyance for heavy goods and reducing the horses' labour; but as the paving is always preferred for heavy carriages, the sides of a road are left for light carriages, and are kept in much better repair than otherwise they could possibly be. It is not overestimating the advantage of the paving, but rather otherwise, to say, that, taking the year through, two horses will do more work, with the same labour to themselves, upon a paved road, than three upon a good gravelled road. If the traffic upon the gravel road is at all considerable, and if the effect of this, in point of expense, is brought into figures, the saving of the expense of carriage will be found to be very great when compared with the cost of the paving. If the annual tonnage upon the Commercial Road is taken at 250,000 tons, and at the rate of only 3s. per ton from the docks, it could not upon a gravelled road be done under 4s. 6d., say however 4s. or 1s. per ton difference, making a saving of 12,500l. or nearly the whole expense of the paving in one year. The introduction of paving, therefore, would, in many cases, be productive of great advantage, by improving the gravel road, reducing the expense of repairs, and causing a saving of horses' labour much beyond what there is any idea of."

3698. *Telford* considers that it would be of advantage to pave a part of the centre of great public roads; and in conformity with this principle, when forming a gravel road, he lays eight or ten feet of it in the centre with stones.

3699. *The parts of the road most desirable to be paved*, according to B. Farey are the sides. "If the centre were paved," he says, "the light carriages would be much an-

thought well-drained land, much after what I would recommend for the form of a road. The object of forming the land into ridges, raised a little in the middle, is the same as that of raising the middle of a road, to prevent the water from settling upon it; and what is sufficient for the ploughed land, is certainly enough for a road. If the road is of good state, four to five inches rise in ten feet is sufficient; gravel and other inferior material will allow a little more. This shape not only assists the water to pass from the centre towards the sides, but greatly contributes to the drying of the road, by allowing the action of the sun and air to produce a great degree of evaporation. Surveyors ought to use a level in giving roads a proper shape, in order that the surface may be of one uniform curvature, without the slightest deviation, in any one spot, from the prescribed line of the cross section."

3680. *The degree of convexity preferred by Mr. Adam is less than that approved of by any of the road-engineers mentioned, unless perhaps Edgeworth.* "I consider," he says, "that a road should be as flat as possible, without regard to allowing the water to run off at all, because a carriage ought to stand upright in travelling as much as possible. I have generally made roads three inches higher in the centre than I have at the sides, when they are eighteen feet wide; if the road be smooth and well made, the water will run off very easily in such a slope. When a road is made flat, people will not follow the middle of it as they do when it is made extremely convex which is the only place where a carriage can run upright, by which means three furrows are made by the horses and the wheels, and the water continually stands there and I think that more water actually stands upon a very convex road, than one which is reasonably flat."

3681 *If a road be high and convex in the middle* Fry observes, no care of the surveyor can prevent the formation of a pair of ruts along the ridge of the road from an instinctive operation of fear every driver will take this track, as being the only part of the road where his carriage can stand upright; and even if it be not so convex as to excite fear, yet the inconvenience of traveling on a sloping road will always produce the same effect.

3682. *The convexity recommended by Paterson on the level ground, where the bottom is dry, should be from one inch to one inch and a half in the yard.* From this, the declivity may increase even to three inches in the yard, just in proportion as the ground increases in wetness but beyond that declivity it would probably be improper to carry it in any instance. If the bottom however is dry sand or gravel, the convexity should be very little indeed. But in all cases, whether wet or dry a road formed on sloping ground, should be very nearly level from side to side. The reasons are obvious. In the first place, it is well known that carriages running quickly over a hill, are more easily overturned than on level ground. It would therefore be dangerous, in this respect alone, were the road to have much slope on the sides. In the next place, as the great end in giving it the convex shape is to run off the water and prevent it from lodging, this is not so necessary on a road formed upon sloping ground, as there the water will not lodge so as to injure it. In his second work (*Letters, &c.*) Paterson observes of the above directions, "In my treatise respecting the form of the road I proposed the slope from the edges of the materials, to the side ditches, to be from an inch to an inch and a half in the yard, where dry; and to increase the slope a little where wet. But by adopting these drains under the road, no greater slope will be required, in any situation, than an inch to the yard."

3683. *The convexity recommended by Stevenson is, where the road passes through a level track of country, an ellipse, "falling from the centre to the verges on either side, at a rate not exceeding an inch and a half perpendicular to a yard horizontal. (Pg. 547.)* But

547

when an acidity in the hue of drought occurs, where carriages are in the greatest danger of being upset, the surface of the road should be kept flat, or with a fall not exceeding three quarters of an inch to the yard, to take the water gently off toward the sides, and prevent it, during heavy rains, from rutting the road in a lateral direction." (*Ed. Essay on Roads.*)

3684. With respect to the order and mode of laying out the materials, there is some difference of opinion. Some begin with the largest, and finish with the very smallest, or with gravel; some lay on the whole at once, and others in two or more strata, and so on. That such a mode of depositing materials could never make a good road is evident; for the reasons given by Mr. Adam and Clarke: the larger stones would soon rise to the surface, and roll about loose on it, the strata, being thus broken up, would admit sand

retain water, which, by the traffic of the road, would render the substratum, in all such places, a mass of mud; and the whole would become bad in proportion to the traffic, the subsoil, and the climate. Marshall is equally wrong in his directions for forming farm-roads, by filling the wheel-tracks with hard materials. In depositing these, he says, the largest and roughest are to be thrown to the bottoms of the wheel-tranches, as foundations for the hardest, which ought to receive the immediate pressure of the wheels, the softest and finest being disposed of in the horse-track. It is evident the continual action of the wheels in the same rut, aided by the water which must infallibly lodge there, would soon work up the larger and rougher stones, and render the traction more oppressive than if no metals had ever been laid there.

3685 *Telford's mode of disposing of the materials of roads* is as follows — Where a road has no solid and dry foundation, it must be constructed anew. Upon the eighteen centre feet of it stones must be put, forming a layer seven inches deep. Soft stones will answer, or cinders, particularly where sand is prevalent. These bottoming stones must be carefully set by hand, with the broadest end down, in the form of a close neat pavement. The cavities should be filled with stone chips, to make all level and firm, and no stone should be more than five inches broad on its face. Over its bottoming of stones or cinders, six inches of stones, of a proper quality broken of a size that will, in their largest dimensions, pass through a ring of two and a half inches diameter, must be laid. The six feet of the road, on each side of the eighteen centre feet (making thirty feet), when formed of a proper shape, may be covered with six inches of good clean gravel, or small stone chips.

3686. *No covering or mixture of any sort is added to the material by Edgworth*, except clean angular gravel, that may insert itself between the interstices of the stones; but no more should be used than what will thus sink to a level with the surface. If the whole were covered with gravel, it would be impossible to discover the defects of the road, till it might be too late. No stones larger than an inch and a half in diameter should be suffered to remain on the road where much inaccuracy in this respect is suspected, an iron ring may be employed as a gauge. In all cases, after the road has been covered with stones, it should be carefully examined, and every stone that is too large should be picked off to be broken smaller.

3687 *The preference generally given to gravel*, Paterson considers to be greater than it deserves, and that the earth obtained from the sides of the road, free of expense, will not only barely answer the purpose, but in most cases equally well, and that on a perfectly dry bottom, it is questionable whether it should not even be preferred to gravel. It is in winter only, and on wet ground that I consider gravel entitled to any preference whatever. (*Treatise*, &c. p. 45.)

3688. *The mode of laying on gravel according to Walker* is to lay it on as it comes from the pit, except the upper foot, or eighteen inches or so, which is screened, but in all cases, whether the material is gravel or hard stone, the interstices between the pieces should be filled up solid with smaller pieces, and the finishing made by a thin covering of very small pieces, or road-sand or rubbish for those interstices must be filled up before the road becomes solid, either in this way or by a portion of the materials of the road being ground down, which last mode occasions a waste of the material, and keeps the road unnecessarily heavy and loose. In the original making or effectually repairing of a road, it is, I think, best that the whole of the proposed thickness be laid on at once, for the sake of the road as well as of the traveller the materials of the road then form a more solid compact mass than when they are laid in thin strata at different times, for the same reason that a deep arch of uniform materials is preferable to a number of separate rings. Laying on a stratum of unsifted gravel, under a sifted stratum, is rather at variance with the doctrine of “a deep arch of uniform materials” and it seems to us, that when a stratum of properly broken stones are to be powerfully rolled, the previous filling up of their interstices with very small matters might counteract the effect of rolling, in squeezing the angular stones into the angular interstices.

3689. *The mode of laying on gravel by M'Adam* is that of scattering with a shovel, and never emptying down cart or barrow-loads on the middle of the roadway, as is generally practised. He completes the stratum by three separate layers, leaving the first to be consolidated by wheels, and in some cases a heavy roller before he lays on the second and the second, in like manner before he lays on the last.

3690 *A covering from four to five inches thick*, according to Fry forms a bed or mass, which is proof against the severe crush of heavy wheels; while in the case of a very thin covering, the stones lying bare upon a hard road, and receiving in this unprotected state the stroke of every wheel that passes over them, like the thin covering on a mill-bed, they are quickly reduced to powder, and disappear. Stones in a thick bed are protected from the immediate destructive grind while stones that are thinly laid on are instantly reduced to powder, either by pressure or grinding.

3691 *Telford's*, in *lifting* broken stones, and also in scattering them on the road, makes

use of a pronged shovel, fourteen inches square, which may be universally recommended for this purpose (fig 348 d). His large hammer (a), small one (b) and gauge for the size of the broken stone (c), are in very general use, as well as the pronged shovel. Hammers may be made of cast iron, where the stones to be broken are about their own weight, the best shape is a narrow oval; the advantage of using cast iron is its cheapness. (*Fern. Mag.* xlii. 159.)

3692. *Telford's level*, for adjusting the declivity of roads from the middle to the sides (fig 349.), is also a very complete implement of the kind.

3693. *The mode of depositing materials by Paterson* is as follows — "Bottom metals should be broken on the road. When they are thus broken, they are, by the force of the hammer firmly bedded into the bottom, and are so closely and compactly beaten together, that they become like pavement. In this state they are not only less liable to sink, but they form a much better bed for the top metals than when they are thrown loosely on. And besides this, when they are put on in a loose manner as is frequently done, the mud more readily works up through the metals in time of rains, and makes a disagreeable road the top metals also are easily beaten down, by the horses' feet and the carriages, through the bottom stones, when loose and open so that the small metals frequently get undermost, and the large ones make their appearance at the surface, very much to the injury of the road. Taking all these circumstances, therefore, into consideration it is of the greatest importance that the bottom metals should not only be much larger in size, but that they also be broken on the road." This may be considered as at variance with several parts of Paterson's second publication, *Lectures*, &c. The road being drained and prepared for the materials, he then directs (p. 80.) to put them on in the following manner — "M'Adam's mode of putting them on, in coats of three or four inches, though good in particular instances, will not do as a universal rule. If the bottom is wet, and the weather rainy, the earth will poach and work up through the materials, in spite of all the attention and care that can be bestowed. I would, therefore, recommend in such cases to put on the first course from five to six inches thick. But then to leave these materials to consolidate, or rather to move and shift about by the wheels and then to be levelled by the rakes, alternately, according to M'Adam's plan, wears away the corners of the stones, by which means they do not unite together and make such a firm road. There were upwards of two miles of road made under my directions lately, on which I caused a course of about six inches to be put. But before opening it to the public, I got a heavy stone roller to ply upon it for four days. This beat and firmed the materials so much, that the wheels of the carriages made little impression upon it. Of course the materials retained their angular points more than in rolling and shifting by every carriage-wheel that passed and there was less labour in raking and leveling the road. This plan, which carries reason on the face of it, I would strongly recommend. As to M'Adam's plan of putting on the materials in shovelfuls, it is certainly good. I used to prohibit putting them on with carts (as in that case you never have the small and the great properly mixed together), and generally put them on with wheelbarrows; but even this does not mix them quite as well as scattering them with the shovel; and as it is of considerable importance to have them well mixed, I would by all means recommend the mode best calculated for that purpose."

3694. *Rolling newly laid on metals* is generally approved of. The roller used should not be less than four or five feet in diameter; a smaller size, especially in the use of gravel, being apt to drag and force the loose materials before it. Some have attempted to keep roads in order by occasionally harrowing and then rolling them; but the best

judges are of opinion with John Farey (*Evidence*, p. 1818.), that a roller cannot be beneficially used upon a road at any other times but after new coating it with materials, or after a frost, or when the sticking of materials to the wheels may have loosened up the stratum.

3686 *Beaton's new theory of roads*, as given in vol. i. of the *Communications to the Board of Agriculture*, is as follows:—Water percolates through porous strata, and is retained by compact strata. Whatever may be the form of the surface, therefore, if there is a porous stratum underneath, the surface will be generally dry. When a new road is to be formed, reduce the natural surface so as the line of a section of it may meet in an angle or ridge in the middle of the road (fig. 550, c), having a slope from thence of

550

about an inch in a foot. The road being thus formed, must be allowed to harden and settle for some time, and then covered to a level, by a stratum (b) sufficiently porous to admit water to pass through it: small drains (c) being formed at the sides, to lead the water from the gutters (d), into the open ditches (e). Over this is to be laid the coat of hard materials (f) which need not be more than 6 or 7 inches in thickness, of stones broken very small, or of the best gravel: it is then to be rolled with a roller, which admits of being loaded, so as to render the surface harder and harder by degrees. The advantages of this construction, Mr. Beaton tells us, are, every part of the road being equally commodious for carriages, and very little repair required. These advantages, however, are by no means obvious.

#### BOOK IV. Paved Roads.

3696 *Causeways and pavements* are chiefly made use of in towns, and may therefore be considered as belonging more to architecture than to agriculture. But as it is the opinion of some of the first engineers, that pavements might be introduced with advantage on the public roads for some distance from the larger towns, we shall shortly consider this subject with reference to that object. Paving, as applied to roads, is therefore to be considered as a substitute for a part or the whole of the metalled part of the road, and not as occupying every part of its width or site, as in the case of streets.

3697 *For roads near capital or great commercial towns*, paving, according to Edgeworth, is the only certain method yet known that gives sufficient hardness, smoothness, and permanency. B. and J. Farey are of the same opinion, and the latter considers it would be proper to pave the sides of all the principal entrances into London. Walker who was the engineer of the Commercial Road, ten feet of the centre of which is paved with granite, and has given great satisfaction for upwards of 16 years, is a great advocate for paving. "The advantage," he says, "of paving part of a road where the traffic is great, and the materials for making roads bad or expensive, is not confined to improving the conveyance for heavy goods and reducing the horses' labour: but as the paving is always preferred for heavy carriages, the sides of a road are left for light carriages, and are kept in much better repair than otherwise they could possibly be. It is not oversteating the advantage of the paving, but rather otherwise, to say, that, taking the year through, two horses will do more work, with the same labour to themselves, upon a paved road, than three upon a good gravelled road: if the traffic upon the gravel road is at all considerable, and if the effect of this, in point of expense, is brought into figures, the saving of the expense of carriage will be found to be very great when compared with the cost of the paving. If the annual tonnage upon the Commercial Road is taken at 250,000 tons, and at the rate of only 3s. per ton from the docks, it could not upon a gravelled road be done under 4s. 6d., say however 4s., or 1s. per ton difference, making a saving of 12,500*l.* or nearly the whole expense of the paving in one year. The introduction of paving, therefore, would, in many cases, be productive of great advantage, by improving the gravel road, reducing the expense of repairs, and causing a saving of horses' labour much beyond what there is any idea of."

3698. *Telford* considers that it would be of advantage to pave a part of the centre of great public roads; and in conformity with this principle, when forming a gravel road, he lays eight or ten feet of it in the centre with stones.

3699. *The parts of the road most desirable to be paved*, according to B. Farey, are the sides. "If the centre were paved," he says, "the light carriages would be much an-

royal; when the gravel road was good on the sides, the heavy carriages would go there, and the light carriages would be driven on the stone from the sides again: if the centre were paved, the carter would be obliged to walk on that road to manage their horses, and would be considerably annoyed by carriages, horsemen, &c. passing: but if the sides of that road were paved, the carter would be enabled to walk on the footpath, and to manage their horses without annoyance."

3700. *Paving the sides* is also preferred by J. Farey, "but not the middle, as has been done on the Commercial Road, the Borough Road and others. My reasons for preferring the sides being paved are, that it is next to impossible to compel the carter to keep upon the pavement in the middle of the road: in too many instances, the fear of damage, from the swift going carriages, occasions them either to draw their carts close to the sides, and walk upon the footpaths, or, what is worse, to leave their horses in the middle, beyond a train of carriages. The sides being paved would enable one of those trains of carriages to enter London on one side of the road, and go out of it on the other, without many occasions to turn out of their tracks: which circumstance of keeping nearly to the same tracks, upon a well-paved road, would not be prejudicial; but on a road formed of gravel is entirely ruinous."

3701. *Walker also prefers paving the sides*, though in the case of the Commercial Road he paved the centre, as already described (3699)

3702. *Stevenson*, as we have seen (3535.), is an advocate for wheel-tracks of stone, as greatly lessening the draught of heavy carriages in the country, and especially in acclivities, and avoiding the irksome noise and jolting motion of causeways in town. Specimens of these tracks have been laid down in Glasgow and they may be seen in various towns in Italy. "The stones of the tracks recommended by Mr. Stevenson, are of a cubical form (fig. 551), measuring only from 6 to 8 inches in the lengthway of the track, and 12 to 14 inches in depth, 18 inches in breadth at the base, and twelve inches on the top or wheel-track. The stones are therefore proportionate in all their dimensions for, unless they contain a mass of matter corresponding to their length, they will be found to want strength and stability. It would hardly be possible to keep slender stone rails in their places, and hence the chief benefit of a connected railway would be lost. On the other hand, very large materials are difficult to be got, and

are also more expensive in carriage and in workmanship than stones of a smaller size. The Italian wheel-tracks are composed of stones 2 feet in breadth, and of various lengths. To lessen the risk of horses falling, these broad stones are kept in a rough state by occasionally cutting grooves with a pick-axe upon their upper surface." (*Edin. Encyc. art. Roads.*)

3703. *Mathews* also has proposed a plan for a stone railway: he proposes that the stones should be in pieces measuring 4 feet 2 inches in length 11 inches in breadth at the top, 14 inches at the base, and 10 inches in depth. He has various modes

of connecting these stones by a mortice and tenon joint (fig. 552.), bevelled so as to prevent the joint from sinking; by a bevelled joint in which the ends of the two rails are made to rest on a centre or intervening block (fig. 553.) and with bevelled and grooved joints, so as to prevent lateral derangement, as well as sinking (fig. 554.) The manner of placing stones on these different methods together, of securing them by a row of rubble camberway stones on each side, and preserving the horsepath between, may be easily conceived. (fig. 555.) Mr. Mathews intended these railways for all the principal highways in the kingdom: but the expense of the plan was one of its chief objections. It has been alleged also, that unless the cubic contents of these blocks bore a greater proportion to their length, they would be deranged by the pressure of very heavy carriages. (*Ed. Encyc. art. Roads.*)

3704. *Paving the whole or any part of a road is entirely disapproved of by M<sup>r</sup>. Adam.* "The measure," he says, "of substituting pavements, for convenient and useful roads, is a kind of desperate remedy, to which ignorance has had recourse." The badness or scarcity of materials cannot be considered a reasonable excuse, because the same quantity of stone required for paving is fully sufficient to make any excellent road any where;

and it must be evident that road materials of the best quality may be procured at less cost than paving stone. The very bad quality of the gravel round London, combined with want of skill and exertion, either to obviate its defects, or to procure a better material, has induced several of the small trusts, leading from that city, to have recourse to the plan of paving their roads, as far as their means will admit. Instead of applying their ample funds to obtain good materials for the roads, they have imported stones from Scotland, and have paved their roads, at an expense ten times greater than that of the excellent roads lately made on some of the adjoining trusts. Very few of these pavements have been so laid as to keep in good order for any length of time, so that a very heavy expense has been incurred without any beneficial result and it is to be lamented that this wasteful and ineffectual mode is upon the increase in the neighbourhood of London.

3705 *The practice of paving roads* has also been adopted in places where the same motive cannot be adduced in Lancashire, almost all the roads are paved at an enormous cost and are, in consequence, proverbially bad. At Edinburgh where they have the best and cheapest materials in the kingdom, the want of science to construct good roads has led the trustees to adopt the expedient of paving to a considerable extent and at an expense hardly credible, when compared with what would have been the cost of roads on the best principles.

3706 *The advantages of good roads, when compared with pavements, are universally acknowledged*; the extension of pavement is therefore to be deprecated as an actual evil, besides the greatness of the expense. Pavements are particularly inconvenient and dangerous on steep ascents, such as the ascent to bridges, &c. A very striking example of this may be observed on the London end of Blackfriars bridge, where heavy loads are drawn up with great difficulty, and where more horses fall and receive injury than in any other place in the kingdom. The pavement in such places should be lifted, and converted into a good road, which may be done with the same stone at an expense not exceeding 10*d* per square yard. This road would be more lasting than the pavement, and, when out of order may be repaired at less than one tenth of the expense which relaying the pavement would require. This measure has been adopted with great success, and considerable saving of expense, in the suburbs of Bristol, where the pavements were taken up, and converted into good roads, about three years ago. The same thing has lately been successfully adopted on Westminster and Blackfriars bridges.

3707 *In preparing for laying down pavements*, the first thing to be attended to, Edgeworth observes, is the foundation. This must be made of strong and uniform materials, well rammed together, and accurately formed to correspond with the figure of the superincumbent pavement. This has no where been more effectually accomplished, than in some late pavement in Dublin. Major Taylor who is at the head of the Paving Board, before he began to pave a street, first made it a good gravel-road and left it to be beaten down by carriages for several months; it then became a fit foundation for a good pavement. The Romans, in preparing for pavement, laid a substratum of masonry in some cases two or more feet thick, and never less than a foot or eighteen inches. This mode is adopted in one or two cases near St. Petersburg, and might be advantageously used in this country, were not the expense an objection. Flanking, broad stones, iron plates, slates, tiles, and brickwork have also been proposed in this country but a consolidated stratum of broken stone of ten inches in thickness is perhaps the simplest and best preparation, especially for the sides of roads. A substratum of sand is sure to be disturbed after the first rains.

3708. *The kinds of stone used in paving* are chiefly granite, whinstone or trap,

either for other pebbles, or water-worn granitic or trap-stones. Walker prefers the granite of Cheshire in that of London.

2709. The size of the stones used in road pavements is constantly from five to seven inches long, from four to six inches broad, and from six to eight inches deep. Walker prefers stones nine inches deep; and Telford is of opinion that the general shape of the stones at present used for paving, and the mode of distributing them, are very imperfect, the lower part of the stones being of a triangular wedge-like shape, which, instead of enabling them to resist the weights which come upon them, easily penetrate into the substratum: the stones are also broken of an unequal size. The remedies for these defects are obvious: they should be as near as possible of a cubical form, the lower bed having an equal surface with the upper face; they should be selected as nearly as possible of an equal size, and they should never be of unequal length on the face. In quarrying and preparing the stones there would certainly be an additional expense in the preparation, because there would be more work required in the dressing, and many stones must be rejected which are now used; but the additional expense would be very well bestowed.

2710. In laying down the stones, each stone, according to Edgeworth, should bear broadly and firmly on its base; and the whole should be rammed repeatedly to make the joints close; the upper and lower sides of the stones should be as near each other as possible, but they should not touch each other laterally except near the top and bottom, leaving a hollow in the middle of their depth, to receive gravel, which will serve to hold them together. This method of paving may be easily executed by common workmen, who may throw in gravel between the stones as they are laid down. It may be easily conceived, that if a grain of gravel inserts into holes that are in stones opposite to each other, it will draw them together. It will be useful to cover a newly made pavement with gravel, which will preserve the fresh pavement for some time from the irregular pressure of wheels, till the whole is consolidated. The stones should be of equal hardness, or the soft ones will be worn down into hollows. In every species of paving, no stones should be left higher or lower than the rest; for a wheel descending from a higher stone will, by repeated blows, sink or break the lower stone upon which it falls.

2711. The regulations for laying down the stones and forming a good pavement are, according to Walker, to have the stones properly squared and shaped, not as wedges, but merely as rectangular prisms to sort them into classes according to their sizes, so as to prevent unequal sinking, which is always the effect of stones, or rows of stones, of unequal sizes being mixed together to have a foundation properly consolidated before the road is begun to be paved, to have the stones laid with a close joint, the courses being kept at right angles from the direction of the sides, and in perfectly straight lines; the joints carefully broken, that is, so that the joint between two stones in any one course shall not be in a line with or opposite to a joint in any of the two courses adjoining. After the stones are laid they are to be well rammed, and such of the stones as appear to be rammed loose should be taken out and replaced by others after this the joints are to be filled with fine gravel, and, if it can be done conveniently the stability of the work will be increased by well watering at night the part that has been done during the day, and ramming it over again next morning. The surface of the pavement is then to be covered with an inch or so of fine gravel, that the joints may be always kept full, and that the wheels may not come in contact with the stones while they are at all loose in their places. Attention to these points will very much increase both the smoothness and the durability of the paving. He has found great advantage from filling up, or as it is called, *growing* the joints with lime water which finds its way into the gravel between and under the stones, and forms the whole into a solid concreted mass. The purpose served by the lime might also be effectually answered by mixing a little of the borings or chippings of iron, or small scraps of iron hoop, with the gravel used in filling up the joints of the paving. The water would very soon create an oxide of iron, and form the gravel into a species of rock. He has seen a piece of rusty hoop taken from under water, to which the gravel had so connected itself, for four or five inches round the hoop, as not to be separated without a smart blow of a hammer; and the cast-iron pipes which are laid in moist gravel soon exhibit the same tendency.

2712. As substitutes for paving stones, pieces of cast iron moulded into the form of the surface of a pavement of different sizes (fig 558 a, d, e) have been tried, but on the whole they are not considered as likely to succeed. They are very hot in summer and more slippery than stone in winter; but what is most against them is, that the water finds its way beneath them and softens the substratum. Thus, at any time of the year, tends directly to produce holes by the leverage of wheels and the feet of animals (357A.); but after a severe frost the effects are ruinous. At all events, this description of pavement does not appear so well adapted for the sides or middle of public roads as that of granite stones prepared in Telford's manner (2708).

3713. Various improvements in laying pavements have recently been devised, such as laying the stones dry or *à l'italien*, using square stones, or stones equally wide at bottom as at top, using stones alternately wider at bottom and top, and joining them with cement (fig. 556.) paving on plates of iron, wood, or stone, or on a mass of masonry, &c. If pavements in towns did not require to be frequently lifted on account of sewers, and water and gas pipes, paving in this manner on a solid foundation would certainly be the best mode but as things are, and even probably if pavements did not require to be frequently lifted, Mr. Adam's roads are found greatly preferable for all broad streets, and where care is taken to keep them clean and in complete repair. In Britain, at least, they will probably soon supersede all common pavements, and all other descriptions of common roads.

557. 3714. Large blocks of granite (fig. 557) have been substituted for common-sized paving stones each block is two or more feet square, nine inches deep, and channelled on the surface in imitation of common-sized paving stones. These are found to answer much better than the cast-iron plates but they are liable to the same objection as to leverage are difficult to replace properly; and as the raised pannels between the grooves will in time wear down to the level of the grooves, they cannot be considered so durable as common square stones, which, after all, appear

the best for general purposes, and, at all events, for paving the middle or sides of highways.

3715. Blocks of stone and also of timber, have been proposed to be laid in iron boxes; but the effect of the granite blocks laid down in Fleet-street does not warrant the expectation of any advantage from either of these modes. Where nothing but light carriages pass over a road, no material is more agreeable than blocks of wood set endways, as is done in many parts of Russia and Germany and this mode of paving may therefore, be considered very suitable for private court-yards, or stable-yards in country residences. (*Newton's Journal*, vol. vii. p. 197.)

3716. The defects of common pavements, and the theory of its wear, are thus given by Edgeworth. "Stones, in a common pavement, are usually somewhat oval, from five to seven inches long and from four to six inches broad. They are laid in parallel rows on the road (fig. 558. a, d) or alternately (a b) as bricks are laid in a wall. On the first sort of pavement, wheels slip from the round tops of the stones into the joints between, and soon wear away the edges of the stones, and their own iron tire. By degrees, channels are thus formed between some of the stones, and in time the pavement is ruined.

3717. On the second sort of pavement (a, b, where the stones are placed alternately, to prevent the injury to which the former method is liable, the wheel (f) sliding sideways, makes a channel between two stones, and is then obliged to mount from the groove which it has made, to the top of the stone opposite to it when it has attained this situation, the wheel may slide sideways, or may go forwards over the top of the stone, till it drops into the interstice between the two next stones. By continual wearing, these ruts become so wide and deep, that the wheel does not touch the stones on either side, nor does it reach the ground between them, but it bounds from one stone to the other, thus jolting the carriage in every direction. This method is not at present in use.

3718. In the pavements last described, the stones are but of a small size but if flat stones of twelve or fourteen inches long (c) are well laid, wheels are not liable to slide into the joints, and if such stones are laid with their longest sides crossing the road, they are less liable to injury but still narrow wheels sometimes fall into the joints between the largest stones, and having in time worn away their own edges, and those of the stones, they will act like wedges, and will displace the stones. No pavement, of the best stone that could be procured, can long resist this action of a narrow wheel. And the only effectual means of preserving pavements is, to increase the breadth of all wheels to at least three inches. Were no wheels narrower a cheap and durable pavement might be made of flat stones, not more than three inches square, provided they were eight or nine inches deep, to give them reciprocally lateral support, for the tire of such broad wheels could never sink between the joints of the stones." (*Edgeworth*.)

3719. Various improved methods of paving have been lately brought into notice. About 1811 or 1812, we suggested the idea of placing the stones on a foundation

of flag-stones or cast-iron plates on a bed of mortar. (Fig. 559.) When this mode is adopted in the streets of cities, the gas and water pipes (a) may be placed in drains, covered with large blocks of granite (b), channelled on the surface to prevent horses from slipping. Access to the pipes might be had by simply lifting these stones, without disturbing any other part of the pavement. (*Gard Mag* vol. v p. 79.)

3730. George Knight has suggested the idea of placing the paving stones with the broadest surface underneath, on a Macadamized foundation, and some streets in the metropolis have been so paved. The improvement has been found considerable but as the rain-water sinks to the Macadamized stratum, and cannot run off through it for want of drains, the mud still works up to the surface. With adequate under-drainage, or with the stones so compact as that the surface-water would run off instead of running through, this plan would be one of the most perfect which has been suggested.

3731. Colonel Macrene recommends pressure, "which may be applied in three different stages of the work first, to harden the ground previously to laying the stones secondly, to fix and depress them when laid, thirdly, to equalise and perfect a pavement after it has been some time in use, by applying the pressure only on the protuberant parts. The machine he proposes for the above purpose is similar to a pile-driver of the smaller kind the weight being drawn up by a rope passing over a single pulley-wheel at the top of the slide shafts, and terminating on the other side in a cluster of smaller ropes or cords, one for each of the six, eight, or ten men employed to work the machine." (*Hints to Peasants*, 8vo. 1836.)

3732. Lieutenant Brown suggests that, after the foundation has been formed in the necessary shape, and the surface rolled or rammed hard, the paving stones, dressed so as to fit close together, should be laid or set in a *thick coat of good mortar*, and the joints grouted with cement, the whole mass would thus become a *solid body*, and the rain would be effectually prevented from penetrating to the foundation, which would remain dry and firm in the position in which it was originally placed. By bedding the stone in mortar, properly placed in the situation in which it is to remain, then grouting the joint, and allowing it to set hard, without afterwards ramming or disturbing it, the pavement will remain immovable and water-tight, until fairly worn out, and save all the expense of an artificial foundation of Macadamized stones or other matter. A grand objection to a Macadamized pavement, in this and every cold climate is, that a severe frost setting in after wet, does *incalculable injury*, owing to its porous state now, as no water can penetrate beneath the surface of this pavement, if properly made, this serious fault is obviated." (*Quar Jour Science*, Jan 1830.)

#### SECT. V. Milestones, Guide-posts, and Toll-gates.

3733. Milestones of the most improved kind are generally formed of durable stone, or cast iron. They ought to have two faces (fig 560.) one to contain the distance from the metropolis of the country to the stone, and the distance from that stone to the next market town, and village or place, and the other the distance from the extremity of the road to the stone, and from the stone to the next market town, and village or place, in proceeding to the metropolis. On a face on the apex of the stone may be the name of the county and hundred, and on the base, the name of the township, parish, and hamlet or village. In some countries of the Continent, as in Wirtensburg and Bavaria, a small open area of 10 or 12 feet in diameter is preserved round the milestones; a bench of stone or turf forms a semicircle, in the radius of which is the milestone, and immediately beyond the bench a row of ornamental trees or shrubs. In several places, every milestone is formed in three steps, the lowest 3 feet 6 inches, the next 3 feet 6 inches, and the last or top of the milestone 4 feet 6 inches. The use of these steps is, to enable people of different heights, travelling alone, and carrying burthens on their backs or heads, to set down these burthens, rest themselves on the benches, and resume the burthens without assistance. In England such an arrangement is unnecessary; but various plans have been suggested for rendering milestones interesting names of hamlets to mankind who lived near; dates of remarkable events; monuments, tombs, statues, small burial places, cottages, almshouses, &c. &c. (*See Gard. Mag.* vol. v.) We should prefer a cottage or a burial place at every milestone, because, as the majority of travellers are on horses or in carriages, they can have little time to peruse milestones; but the cottage might afford protection to the foot traveller, and a glance at the burial

560

place would afford matter of reflection to all. "It has been suggested to us that milestones might be made larger in the form of an obelisk or sarcophagus, on the model of an ancient classical or other building, or in other forms, and that there might be inscribed on them the names and dates of events which took place, or of great men who lived, in the neighbourhood and that, in addition to these, there might be inscribed on each milestone, or structure serving the same end, maxims of conduct, or funda-

mental principles of science. Thus, on some roads, the milestones might exhibit sculptured reliefs, representing a historical series, either of events in the history of that part of the country, in the life of some eminent character who had lived there, in the progress of discovery in some art or science of the human mind generally, or in general history. If all the proprietors on a line of road were agreed, a group of exotic trees and shrubs might be planted as a back ground to a small area, which might contain the milestone and by planting every group to one genus of timber tree, and one or two fruit trees,

considerable variety would be produced, and the botanical interest of the road kept up for many miles. Small burial-grounds round milestones would, we think, be unobjectionable and, indeed, we do not think they could be better placed: and tombstones there, or any where along the road-side, would attain their end more effectually than in churchyards, and, at any rate, would be what is called classical; which is an excellence to be aimed at, and which is beneficial in a certain stage of progress, but too often, in architecture and in sculpture for example, an impediment to improvement, by being considered the highest degree of excellence. Some one has proposed to build cottages as milestones, and to that plan and to various others we have no objection, to a certain extent, the danger being the production of sameness, by adopting the same plan every where." (*Gard. Mag* vol v p. 117)

3724. *Guide-posts.* Wherever one road branches from another there ought to be a guide-post; and it is not a little remarkable that in this improving age, when every street and lane in towns is so carefully named, that so little has been done in the streets and lanes of the country. The posts which bear the names ought, where the expense is not an insuperable object, to be of iron, on account of its durability. Swaine proposes to have the posts hollow cylinders of cast iron, and the letters to be also of iron, with the space between them open, "so that the light may be seen through them; by which means the characters of this hand-post will be legible at night, by viewing them against the sky unless it should be exceedingly dark. The direction of the road is denoted by the manner of disposing the letters thus, in a guide-post between London and Windsor (*fig* 561 a), the letters of the word London are reversed, to denote that the direction of London is to the left hand the word Windsor in the line beneath is not reversed,

as that town shall be understood to lie to the right hand; the number of miles to each place is shown by figures placed beneath each word. The same object may also be attained in the more obvious manner in general use (fig. 561 &c.).

561

5725. Toll-gates and gate-houses have also partaken of the improvement of the age. The form and hanging of the gates have been scientifically treated of by Parker who may be considered as having arrived at a high degree of practical excellence. For his general principles, and the details of his compensation hinge for turnpike-gates, see § 3061, 3082, and his valuable *Essay on Hanging Gates* &c., ed. 3., 1826.

5726. Gates or toll-houses have been materially improved, both in point of internal comfort, and as objects of taste. Some of those in the neighbourhood of London are elegant objects. As an example we shall select that at Edgeware. (fig. 562.) On

562

the summit of the cupola of this house there was originally a lamp with three burners and three separate reflectors. Two of the reflectors directed the light along the road in opposite directions, to show what might be coming or departing on either hand; the third reflector threw the light directly across the road, and down on the gate, for the purposes

of the gate-keeper and those passing through. After this light had remained between two and three years, it was taken down, as being too brilliant and as having frightened some horses, but it might surely have been softened, so as to be retained. Where there are two gates, as in various examples, a lamp post is very properly placed between them, which thus answers all the purposes of the cupola and triple lamp at Edgeware.

# SECT. VI. *Preservation and Repair of Roads*

3797 *The preservation of a road depends in a great measure on the description of machines and animals which pass over it, and on keeping it dry and free from dust and mud. The repair of a road should commence immediately after it is finished, and consists in obliterating ruts the moment they appear, filling up any hollows, breaking any loose stones, and correcting any other defect. After cleaning and this sort of repair have gone on hand in hand for a longer or shorter period, according to the nature of the materials and traffic on the road, a thorough repair or surface-renewal, by a coating of metal of three or more inches in thickness over the whole of the road, may be required.*

3798. *To preserve a road, by improving the wheel carriages which pass over it, all agree that the wheels should be made broader than they usually are, and cylindrical; that carts with two horses abreast are less injurious than such as are drawn by two horses in a line; and that it would be an advantage to have the axletrees of different lengths.*

3799 *Edgeworth, upon a careful examination, concludes that the system of rolling roads by very broad wheels should be abandoned, and that such a breadth only should be insisted upon, and such restrictions made as to loading, as will prevent the materials of the road from being ground to powder or from being cut into ruts. With this view the wheels of carriages of burthen should have fellows six inches broad, and no more than one ton should be carried upon each wheel.*

3790. *Ferry is of opinion, that six-inch cylindrical wheels, or under, are the most practicable and useful, provided the projecting nails are most rigidly prohibited, which can never be done but by a penalty per nail upon the wheelers who put in those nails, and upon the drivers of the carriages who use such roughly-nailed wheels.*

3791 *Telford thinks that no waggon or cart wheel ought to be of less breadth than four inches, and that in general no carriage ought to be allowed to carry more than at the rate of one ton per wheel "when it exceeds that weight," he says, "the best materials for road-making must be deranged and ground to pieces."*

3792 *Peterson is a warm advocate for broad wheels. "If the wheels were used double the breadth that they are at present," he says, "they would act as rollers upon the materials, binding them together and consequently the surface would remain always smooth and free from ruts, and the waste or decay would, of course, be exceedingly little." All broad wheels, however should be constructed differently from those that are in*

common use (*fig 563. a*). Those in common use, whether broad or narrow, are generally *disted* (as it is called) on the outside, and the ends of the axle-tree bent a little downwards. This causes the wheels to run wider above than below; and the reason, I believe, for adopting this plan was to allow people to increase the breadth of their carriages, and yet the wheels to run in the same track. Upon this plan the edges of the wheel, to run flat

upon the road, must be of a conical shape, the outer edge being of a less diameter than the inner one. Any bad effect arising from this is, indeed, very little felt from the narrow wheels but as they increase in breadth, the evil increases in the same proportion. "A conical wheel," says Edgeworth, "if moved forwards by the axle-tree, must partly roll and partly slide on the ground, for the smaller circumference could not advance in one revolution as far as the larger. Suppose," says he, "the larger revolution sixteen feet, and the smaller thirteen feet, the outer part must slide three feet, while the carriage advances sixteen, *i. e.* it must slide nearly one fifth of the space through which the carriage advances, — thus, if loaded with ten tons, the horses would have two tons to drag, as if that part of the weight were placed on a sledge." The same thing has been ably and beautifully demonstrated by Cumming (*Essay on the Principles of Wheels and Wheel Carriages, &c.*), and is very easily illustrated take, for instance, the *frustum* of a cone, or a sugar loaf from which you have broken off a little bit at the point, then set this a rolling upon a table, and instead of going straight forwards it will describe a circle; and if you will put a pin or axle-tree right through the centre of it, and upon that axle cause it to move straight forwards, the smaller diameter must slide instead of rolling. It is evident, therefore, that the rims of the wheels ought to be of a cylindrical form (*fig.*). Edgeworth states, in relation to this, that, from the testimony given to the committee of parliament, cylindrical wheels and straight axle-trees have been unequivocally preferred by every process of science and judgment.

3733. *Farey* finds the Whitechapel road more injured by broad wheels than any other, owing to these wheels being horizontal and vertical, and not running flat, and the middle tire projecting above the others, with rough sills.

3734. *Counting* has proved experimentally before the commission of 1800, that when the rim of a wheel is made truly cylindrical, so as to have an equal bearing on its whole breadth, the resistance to its progress on a smooth road is not increased by increasing its breadth. With regard to the immense saving that would accrue to the nation, *Jamoy*, in his report, says, "I may venture to assert, that by the exclusive adoption of cylindrical broad wheels and flat roads, there would be a saving of one horse in four of seventy-five per cent. in repairs of roads, fifty per cent. in the wear of tire and that the wheels with spokes alternately inclined would be equally strong with conical ones, and wear twice as long as wheels do now on the present roads." But, over and above the preference due to such wheels, in respect of public roads, they are no less preferable when applied to purposes of husbandry. Besides the great resistance to the draught occasioned by the sinking of the narrow wheels on soft land, every farmer knows what injury is frequently done to subsequent crops by such poaching and cutting up of the land. But this is not all. Many a field of beautiful pasture, when subjected to the destroying operation of the narrow wheels, is very much injured, both in respect of the appearance and of the crop, which would be entirely prevented by using broad wheels. Thus it has been stated, with regard to the introduction of the use of broad wheels, that the saving on the incidental repairs of the road would be immense, that the roads would uniformly retain a smooth and even surface, which would greatly contribute to the comfort of the traveller and the ease of the draught that in husbandry also the advantages would be great. In short, that, in every point of view the benefits which would be derived in consequence would be paramount to every thing that could be urged in favour of the narrow wheels.

3735. *Mr. Adam* thinks a waggon wheel of six inches in breadth, if standing fairly or the road with any weight whatever would do very little material injury to a road well made, and perfectly smooth. The injury done to roads is by these immense weights striking against materials, and, in the present mode of shaping the wheels, they drive the materials before them, instead of passing over them. If a carriage passes fairly over a smooth surface, he says, it cannot hurt the road, but must rather be an advantage to it, upon the principle of the roller. On being asked, "Are you not of opinion that the immense weights carried by the broad-wheeled waggons, even by their perpendicular pressure, do injury by crushing the materials?" he answered, "On a new-made road the crush would do mischief, but on a consolidated old road the mere perpendicular pressure does not do any. But there is a great deal of injury done by the conical form of the broad wheels, which operate like slogging instead of turning fairly. There is a sixteen-fath wheel waggon, which comes out of Bristol, that does more injury to our roads, than all the travelling of the day besides."

3736. With regard to regulating the weight to be carried on wheels, *Farey* judiciously observes, that though it is not easy to state any one scale which would be generally applicable for each breadth of wheels below six inches, there should be a rate fixed, which would apply to ordinary or gate tolls and at the weighing machines additional or what may be called machine tolls should be levied upon all carriages which exceeded the weight, to be regulated in an increasing scale for each breadth of wheel, so as very greatly to discourage, but not vainly to prohibit the occasional carrying of large weights upon any wheels.

3737. *Axletrees of different lengths* have been proposed by some engineers with a view to preserving the roads. On this subject *Paterson* observes, "At present the axles of all kinds of carriages are made to one length, so that their wheels all run at the same width, and in the same track, than which nothing could be more fitly devised for the destruction of the roads. I would, therefore, propose, that the length of the axletrees should be so varied, that the wheels of the lighter description of carriages should run two inches narrower than the present track and that the axles for the more weighty carriages should be increased in length, so that their wheels should run from one to four inches beyond the present track. I would also propose, that mails, and other heavy coaches, should be so constructed, that the hind wheels should follow, either two inches within, or two inches outside, the track of the fore wheels, as might be considered most proper. Were the axletrees of all kinds of carriages to be of various lengths, as here proposed, we should have no rutted roads. The stones now displaced by the wheels of one carriage, would be replaced again by the next carriage that came up, having its axle of a different length, and in the same manner would the hind wheels repair the injury done by the fore wheels of a carriage. If this plan were to be acted upon all over the kingdom, it is evident that it would have a very beneficial effect on the roads and if it should be found thus to contribute to keeping the roads smooth and even, it is also evident that it must contribute, in the same proportion, to the comfort of travellers of every description, and also to the ease of the beast of draught."

3733. *J. Fry* is of opinion that varying the length of axles, so as to prevent their running in the same track, would be very beneficial. This he particularly stated to the Board of Agriculture, with an example of the tolls over a new road in Duryshire, which are regulated according to the length of the axle.

3738. *The division of weight* has been proposed by *Fry* as a means of preserving roads: that is to say, the division of the power, which any carriage may possess, to crush or destroy the materials of the roads and the division of the power, which any carriage may possess, to resist the power of the horses drawing such carriage. "A man can break an ordinary stick, an inch in diameter across his knee, but if he tied ten of these sticks together, he could not break them if he tried ten times, nor if he tried a thousand times although, by these thousand efforts, he might have broken a thousand such sticks separately. A stone might be of such a size and texture that a strong man with a large hammer might break it into pieces at one blow while a boy with a small hammer, striking it with one tenth part of the force, might strike it a thousand times, applying in the whole one hundred times the power upon it that the man would have done, without producing the same effect. So it is with the pressure of wheels on the materials of the roads. Suppose a stone, the size of a man's fist, to be detached on a firm part of the road, and a waggon-wheel, pressing with the weight of two tons, were to pass over it, the consequence would be that it would crush it to powder. But suppose these two tons to be distributed into forty wheelbarrows, of one hundred weight each, and they were to pass over over it succession, the only effect likely to be produced would be a trifling rounding of its corners nor would probably five hundred such wheelbarrows, of twenty-five tons, crush the stone so completely as the single waggon-wheel. Nor do I think that five hundred gig or one-horse chaise wheels, of four hundred weight each, in all one hundred tons, would so completely destroy the cohesion of the stone as the single crush of the heavy wheel. Conceiving therefore, that the destructive effect of pressure on the roads increases, from the lowest weights to the highest, in a very rapidly increasing ratio, I think that all reasonable ingenuity should be exercised, so to construct our carriages, as for each wheel to press the road with the least possible weight that the public convenience will allow."

3740. *A great weight in one rolling mass* (fig 564) *Fry* continues, "has a tendency

564

to disturb the entire bed of the road, whether it be on a six-inch wheel or on one of sixteen inches, and whether on conical (fig 563 a) or on cylindrical wheels (fig 563. b). Under all these considerations, I am satisfied that the only grand desideratum, on behalf both of the roads and the horses, is light pressure and therefore any dependence on breadth of wheels, as a security against the destructive effects of pressure, is in my opinion fallacious. I wish here to be understood as applying these remarks upon a supposition that wheels were made upon the most philosophical construction; that is to say, perfectly cylindrical (fig 563. b) and that they stood perfectly upright or vertical. The present system of broad wheels I consider a system of mere mockery."

3741. *Fry* proposes to attain his principle of the division of power by the adoption of light one-horse waggons with six or eight wheels which in our opinion are of very questionable advantage, all things considered, compared to one-horse carts to carry one ton, and four wheel waggons to carry four tons. "One-horse waggons," he says, "fully embrace the principle, and the labour of the horses would be much more efficiently applied than at present. If light one-horse waggons were constructed, to weigh eight hundred weight each, and these were charged with a load of sixteen hundred weight each, a good ordinary cart-horse would travel England over with such a load drawing but as much net weight as the ten horses in a heavy waggon take each in gross weight, and the roads would never have a pressure on one point, exceeding six hundred weight. The only objection to such carriages that I see is, that each must be attended by a man. [There is no reason for this in Scotland one man always drives two single-horse carts.] But were they adopted, roads would last, I will not say ten times as long, I think they would last a hundred times as long, as they now do. Carriages so constructed ought therefore to pass at the lowest possible rate of toll. The next mode is by the use of carriages with six or eight wheels. About twenty years ago there were several stage-coaches constructed in this manner. Two eight-wheel coaches plied some years between Bath and Bristol; and they were so constructed that each wheel supported its share of the load, carrying its proportion and no more, over every obstruction. The consequence was, that when a wheel passed over a stone two inches high the middle part of the carriage rising only an eighth part of two inches, or one quarter of an inch, they were passing the easiest coaches in passenger that ever were met in. They had, however, one defect in their construction; which was, that the two hinder axles being fixed, whenever the coach varied from a straight line on the road, the hindermost pair of wheels must have been dragged sideways. Now the six-wheel coaches were constructed in this respect, I had no opportunity of observing."

3743. Double shafts have been proposed by Edgeworth, Merton, and some others, as likely to divide the traction of draught cattle. R. Farry considers single shafts in waggon very injurious; the horses follow in one track, in the centre of the carriage, and the wheels also follow each other in their tracks, and rut the road. If there were double shafts, they would naturally avoid former wheel tracks, which would be less injurious to the road.

3744. J. Newcomb is in opinion with his brother, and thinks that some abatement of tolls might be made to those carriages which now generally use single shafts, like the farmers carts and waggons, on their adapting double shafts, so that all their horses may draw in pairs. This being applicable even to three-horse carts, so far as the two foremost are concerned. Large machines, for the reasons here alluded to, as they all draw in pairs, and very seldom follow in any previous and deep rut, do far less damage to the roads than otherwise would happen; their springs also, and swiftness of motion, contributing, very materially to lessening their wear of the road.

3744. Roads are generally repaired by manual labour but various machines have been contrived for this purpose. The snow-plough is a well-known implement, consisting simply of two boards placed on edge in the form of two sides of a triangle, and drawn by a hook attached to the apex. The common harrow, followed by the common roller has been used for levelling roads broken up by ruts, and a studded roller has also been lately invented for this purpose.

565

3745. Herriot's road harrow (fig. 565) has been used in some places, for dragging over roads when much out of repair to replace the stones or gravel disturbed by wheel carriages. "A man, a boy, and two horses, will do three miles in length in one day completely harrowing down the quarters, and drawing the stones together which, by means of the mould-boards, are dropped into the ruts far better than a man can stub them in."

3746. To prevent the formation of ruts in roads, and for use in lanes and unmetalled farm roads, Beaton

566

suggests the idea of placing a roller between the other wheels (fig. 566) and so strongly secured to the axle tree, as to be able to support the whole weight in the cart when necessary. This roller he proposes to call a protector and he thinks it will be much more easily drawn than two wheels running in deep ruts. (Com to H. of Ag. vol. I. p. 124)

3747. The cleansing of roads is affected by scraping, sweeping, watering, and washing.

3748. Scraping is an operation universally necessary to keep roads clean, by the removal of mud in wet weather dust in a very dry season, and snow in winter. It has been performed by machinery and on a well made road,

this mode might be attended with a considerable saving of labour. Were the scraping board edged with a brush of wires, or even of burch spray, the work, even on a road somewhat irregular, might be done to great perfection. Both in scraping and sweeping, care should be taken as soon as possible to dispose of the mud or dust, either in making or keeping up the sides of the road or fence mounds, or in such other way as circumstances may direct. Hand scrapers are commonly made with iron plates; but a plate of board is considered less likely to raise the surface of the road,

567

3749. The scraping machine (fig. 567) is the invention of John Beeson, Esq., and consists of an oblong frame of iron, supported on three wheels, two of which are cast-iron carriage wheels, about three feet in diameter, resting on an axle fixed to the frame; the third is a small cast-iron wheel, placed under the centre of the front bar of the frame. Below the frame, and obliquely to it is placed the flexible scraper,

consisting of a number of plates of sheet-iron, strung in a line, and connected together by small bolts. On the back of each plate is bolted a piece of iron, in the shape of the letter S, provided the stem of this iron S is bent in the upper end of the plate, and then bent forward in a horizontal direction to a short distance in the frame parallel to the scraper, at the distance of about eighteen inches from it, to which it is joined. By this arrangement, when the machine is moved forward, the sheet draws after it the series of plates forming the scraper, which being attached to each other by plates, each plate acting as a rake, each plate has sufficient freedom of action to adapt itself to the inequalities of the surface. By this, each plate, in passing, is fixed to the shaft, by which any degree of pressure required can be given to the scraper. As the machine proceeds, a portion of road, equal in width to the quadrilateral figure of which the scraper forms the diagonal, is cleared, and the mud or dirt, as fast as it collects, is dislodged by the oblique surface of the scraper and finally jet in a line on the off side of the machine. This process is commenced near the centre of the road, and the machine, having given a convenient distance in a straight line, is turned and brought back on the other side of the centre, removing the dirt in an opposite direction. For the next course the machine is brought to the side where it first acted, and removes the dirt from a like portion of ground, and with it the line formed by the preceding course. This is continued until the scrapings are brought to the side of the road. The manager is enabled to lift the scraper by turning a wooden roller fixed above it, and attached to each plate by a corresponding chain. This is done in order to pass over parts of roads recently repaired and, when going to work or returning, the plates are kept in this elevated position by a ratchet and catch at the end of the roller. A curved scraper is attached to the back part of the frame at the off-scraper, to be used only during the last course of the machine, for the purpose of collecting the scrapings into heaps ready for removal. This machine, drawn by two horses, and attended by one man will clean five miles of road, twenty four feet wide, in eight hours. Two additional men will be required to throw the scrapings off the road, and clear the water courses. The same work would require twenty five men per diem, with scrapers, according to the present method. (*Gard Mag* vol. v.)

3750. *Sweeping*, as a mode of cleaning roads, is chiefly applicable to pavements, to side railways, whether of stone or iron, and to footpaths. On country roads, sweeping might be required to keep the paved or rail-laid parts, where such existed, free from small stones or gravel which the feet of cattle, &c. might scatter over it from the metalled part.

\*3751. The *sweeping machine* (fig. 558), also the invention of Mr. Bone, has a frame similar to that of the scraper supported in front by two common wheels about four feet in diameter and behind by two

558

small iron wheels with vertical axes, one under each corner. Within the frame, and diagonal to it, is the cylinder of brooms, consisting of five rows of brush, each row secured between two boards by screws, and attached to an axle by radiating arms of cast-iron. This receives a rotatory motion from the carriage wheels, by means of a bevelled tooth wheel fixed on their axles, working in another half in use on the axle of the brooms. When the machine is drawn forward, the brooms are thus made to revolve twice to each revolution of the carriage wheels, and in an opposite direction to them. The brooms are regulated so as to bear more or less on the ground, according to the state of the dirt, and, as the brush wears shorter, they can readily be drawn out from the centre, in order to preserve a proper bearing. The dirt is removed from the space over which the brooms pass to the right or off-side of the machine. Like the scraper, the work is commenced near the centre of the road or street, and carried on in a similar manner. When this machine is wanted to proceed without sweeping, the larger bevelled tooth wheel is drawn out of gear by a lever for that purpose. The brooms are covered and the frame enclosed by oil-cloth, to prevent any splashing or dirt from escaping beyond the machine. This machine, with the same power and attendants as the scraping machine, is capable of cleaning three miles, twenty feet wide, daily. (*Gard Mag* vol. v.)

3752. *Watering*, where applied to roads, is more for the sake of laying the dust than of cleaning or preserving them. Some consider it injurious. R. Farre considers that watering the Whitechapel-road in summer and especially before May and after August, is very injurious, by separating the stones, owing to the softening of the loam, and so making the road spongy and loose. In winter, however, he waters, and for the following reasons: — "After the most careful sifting of the gravel, a small quantity of heavy dirt will unavoidably still adhere to the stones and this loam, together with a glutinous matter which accumulates in the summer from the dung and urine of the cattle (which accumulation the summer watering has a tendency to increase), occasions the wheels to stick to the materials, in certain states of the road, in spring and autumn, when it

is however wet and dry, particularly in heavy foggy weather, and after a frost; by which sticking of the wheels, the Whitechapel-road is often, in a short time, dreadfully torn and heaved up; and it is for remedying this evil that I have, for more than eight years past, occasionally watered the road in winter. As soon as the sticking and tearing up of the gravel-stones is observed to have commenced, several water-carts are employed upon steep parts of the road, to wet the lumpy and glutinous matters so much, that they will no longer adhere to the tire of the wheels, and to allow the wheels and feet of the horses to force down and again fasten the gravel-stones. The traffic, in the course of four to twenty-four hours after watering, forms such a sludge on the surface, as can be easily raked off by wooden scrapers, which is performed as quickly as possible; after which the road is hard and smooth. The advantages of this practice of occasional winter watering have been great; and it might, I am of opinion, be adopted with like advantages on the other entrances into London, or wherever else the traffic is great, and the gravel-stones are at times observed to be torn up by the sticking of the wheels.

3753. *One of the best constructed watering barrels (fig. 569.)* is that used on the Whitechapel-road, in which the water is delivered with the greatest regularity from a cast

569

iron trough (a), so as to cover a space of nine feet in width. The water is turned off and on by a lever at the fore-end of the barrel (b) in the usual manner.

3754. *Washing or flooding roads*, with a view to cleaning them, has been proposed by Jessop and some other engineers; but it is evidently a mode that can only be adopted in particular situations, and the advantages which it would have over clean scraping does not appear.

3755. *Rolling*, as a mode of preserving roads, is recommended by various writers on the subject and appears to be useful on some roads after being loosened by frost. In general, however, it is chiefly applicable after repairs, such as filling in ruts or laying on a coat of new materials. Rolling has also been employed to consolidate snow on roads; it is said to indurate the snow so much, that it becomes a smooth hard body on which the wheels of carriages make but little impression, and the materials of the road are preserved. When a thaw happens, the wheels of the snow is scraped off by snow-ploughs or scrapers, and not being allowed to melt on the metals, they are said to remain unloosened. This plan is said to be general in America, and appears to have been tried, in one instance, in the north of Scotland, with success.

3756. *A road roller* should be of large diameter, perhaps not less than five feet: to facilitate its turning, it may be made in three lengths, and the only material is cast iron, with a large wooden box over.

3757. *Rollers or machines for expediting roads* (fig. 570) consist of three cylindrical rollers, mounted upon axles, in a frame, to be drawn by one or more horses. The rollers are placed obliquely side by side, but turning in parallel positions; their axes meeting a little behind each other: these rollers are intended to pass over the surface of the road, for the purpose of pressing the broken stones, gravel, and other materials, close together, so as to produce a solid or compact road with a smooth surface. In the front of the rollers a long scraper is placed, crossing the stones obliquely, for the purpose of collecting up and transporting away the sand, and the dirt, to the side of the road: and at the back part of the apparatus there is a perforated cylinder, intended to take up the water, or muddy parts of the road, and deposit

It is a swiveling bar within. *Fig. 570*, is a view of the machine, or apparatus, as seen on the top; *a a a*

are the three cylin-  
ders for pressing the  
loose stones of the  
road together. As  
the apparatus is  
drawn along, these  
cylinders revolve  
upon their axes,  
which are mounted  
in the frame *b b b*.  
There is a small  
guide roller or  
wheel in front of  
the frame to which  
the shafts are at-  
tached, and by  
which the appara-  
tus may be turned  
round, or guided in  
a curved course.  
*d d* is a thin plate  
of iron placed ob-  
liquely across the  
machine, in front  
of the rollers. It is  
attached to the  
framing by rods and

screws, and is thereby made adjustable to any height, so as to scrape the surface of the road evenly. The foremost end of the scraper is curved, for the purpose of preventing the escape of the mud, which, being collected as the machine advances, runs along the inclined surface of the scraper, and is conducted to the side of the road. Thus the mud is proposed to be scraped off the surface as the apparatus advances; and the materials of the road compressed and hardened by the traversing of the rollers. It may be added, that in order to increase the pressure of the rollers, a box, to be affixed to the framework, is proposed to be placed over the rollers, which may carry stones, or other heavy materials, that might be used in making or repairing of the road. Under some circumstances, the patentee proposes to adapt to the apparatus the auxiliary cylinder *e*, which is made to revolve upon its axle as it rolls along the road, and is attached to the former by a frame *f f*; this cylinder *e* is perforated all over its surface with holes, or slots, and when it passes along the road, the mud, which is conducted to it by the scraper *g g*, passes through these holes, or slots, to the interior. *Fig. 571* is a side view of this cylindrical roller (*e*) attached to the frame *f f*, within this cylindrical roller the box *h* is suspended, swiveling upon pivots, and as the roller goes round, the brush *i* removes the mud from the cylinder, and causes it to fall into the box below. When the box is filled with mud, it may be discharged through the door *k*. (*Newton's Journal*, vol. xii. p. 57.)

3758. *Marsden*, on the subject of repairing roads, observes, that the best service of the surveyor is to keep their surfaces smooth and even, so that rain-water may find a free and ready passage to its proper drain. Ruts and hollow parts are to be filled up, level or even with the general surface, as often as they are formed. This attention is more especially requisite to a new-made road, whose bed and foundation are not yet fully confirmed. But in every case, and at all times, a solicitous regard is due to this most important, yet most neglected, part of road-surveying. Much expense of materials and labour may thereby be saved, and the great end of road-making be fully obtained, namely that of rendering the road, in all seasons, easy, safe, and pleasant to the traveller.

\*3759. *To keep a road in repair*, Edgeworth observes, it will for some time require the attention of the maker, ruts will be continually formed in the loose materials, these must be sedulously filled up, and a small sprinkling of river gravel should be added. All stones larger than the rest should be removed and broken smaller; and no pains should be spared to render the whole as compact and smooth as possible. At a moderate distance from the capital, if no wheels of a smaller breadth than six inches, and if no greater load than one ton on each wheel, be permitted to pass on it, a road will last a long time, and may be kept in constant repair at a moderate yearly expense.

3760. *The repair of a road* which has been well made, or after it has been put into a good state of repair, *Paterson* observes, requires attention more than expense. No more metals ought to be used for the incidental repair of that road ever afterwards, than are just equivalent to the decay of the road. And in order that the decay of the old, and of course the supply of new, metals may be as little as possible, it is of the greatest consequence that the road never be allowed to get rutted for, besides the unpleasantness of such a road to the traveller, it is a fact not generally thought upon, that the lateral rubbing of the wheels into the ruts will wear and grind down more than double the metals that would be destroyed on a smooth road, where the only friction of the wheels is that of rolling over the metals. Besides, when a road is much rutted, it not only retains the water and consumes a greater quantity of metals (as has been noticed) but the rubbing and jolting of the wheels into the ruts wears down the iron of the wheels, fatigues the beast of draught, and also wears harness, &c., much sooner than when the road is smooth. All these, and much more, are the bad effects of a rutted road. Having premised thus much, I shall next advert to the method to be adopted in order to keep the road free from ruts, at as little expense and labour, and with as few metals, as possible."

bricks small, as above described, being angular, will fit together. In the way a road, whenever well made may be preserved in constant repair at a small expense.

3776. *Partial resurfacing.* Where the breadth of that part of a road, which alone has been formed of hard materials, and over which the carriages commonly pass, is less than eighteen feet, it must be widened with layers of broken stones to that breadth first digging away the earth, and forming a bed for them with pavement and broken stones at least ten inches deep. Near large towns the whole breadth of the roadway should be covered with broken stones.

3778. *Day labour.* By day wages ought, as far as possible, to be discontinued in repairing roads. The surveyors should make out specifications of the work of every kind that is to be performed in a given area. This should be let to contractors, and the surveyors should take care to see it completed according to the specifications, before it is paid for. Attention to this rule is most essential, as in many cases not less than two thirds of the money usually expended in day labour is wasted.

3780. *The best seasons for repairing roads* are generally considered to be autumn and spring, when the weather is moist rather than otherwise.

3781. *R. Percy prefers laying on gravel* when the road is in a moist state, immediately after the road has had a scraping, in consequence of there being upon the surface of the road a small quantity of dirty matter and broken gravel, which then form a sort of cement for the gravel to fix in.

3783. *Walker considers the best season for repairing roads* to be the spring or very early in the summer when the weather is likely neither to be very wet nor dry; for both of these extremes prevent the materials from consolidating, and therefore cause waste, and at the same time either a heavy or a dusty road but if done as the time he has recommended, the roads are left in good state for the summer and become consolidated and hard to resist the work of the ensuing winter.

3783. *The seasons for repairing preferred by Paterson* are also spring and autumn. "Although it is proper," he says, "at all times of the year, to put on a little metals whenever any hole makes it appear so, yet in the drought of summer this will seldom be necessary. In summer the roads are less liable to cut but if, at some places, a little fresh metals may be necessary no more should be put on than are barely sufficient to bring these holes to the level of the rest of the road. Metals that are put on in the drought of summer do not soon bind together. Until such time as there is rain sufficient to cause them to land, they will keep shifting and rolling about, and make a very unpleasant road to travel on. The most proper times of the year to put on any quantity of metals are about the months of October and April, as they always bind best when the road is neither too wet nor too dry. When they are put on about the month of October, they become firm before winter, and with a little constant attention, the road will be easily kept in good order until the spring and if it has been the case that the road has not been sufficiently attended to during the winter and that it has got into a bad state towards the spring, by putting on fresh metals about the month of April sufficient to bring it into smooth surface order it will be very easily kept in this good state throughout the summer."

3784. *M<sup>r</sup> Adams*, on being asked, "Would you prefer repairing old roads in dry weather or in wet weather?" answers "In wet weather always. I always prefer mending a road in weather not very dry."

#### SECT. VII. Railroads.

3785. *Railways or tramroads* are not intended to be considered here as connected with mines, canals, or other works which come directly under the province of the higher branches of engineering but merely as substitutes for the whole or a part of the metallised surface of common roads. The necessity of an expeditious and cheap mode of conveying coals from the pits to the ships had, as early as the year 1676, introduced the use of wooden railways for the waggons to move upon between the Tyne river and some of the principal pits, and these by degrees became extended to a great number of other coal-works. They were first solely employed for transporting coals to a moderate distance from the pits, to the places where they could be shipped, being universally made of wood. By degrees they were, however, carried to a farther extent, the scarcity of wood, and the expense of their repairs, suggested the idea of employing iron for the purposes of unproving these roads. At the first, flat roads of bar iron were nailed upon the original wooden rails, or, as they were technically called, *sleppers* and thus, though an expensive process, was found to be a great improvement. But the wood on which these rested being liable to rot and give way some imperfect attempts were made to make them of cast iron, but these were found to be liable to many objections, until the business was taken in hand by Outram, an engineer at Butterly Hall, Derby shire, who contrived, at the same time, so far to diminish the expense, and improve the strength of the road, as to bring them to a degree of perfection that no one who has not seen them can easily conceive could have been done. This having been carried into execution in a few cases, and found to answer has been improved upon and simplified by practice, till it is now brought to such a state of perfection as to have given proofs that it admits of being carried much beyond the limits of what was for many years conceived to be possible, and to afford demonstrative evidence that it may be in future employed to a wider extent still, to which no limits can be at present assigned or foreseen.

3786. *Railways are of three kinds*, flat, edged, and suspension railways. The flat railway is composed of pieces of timber four or five inches square, called rails or of pieces of cast iron, of about four inches in breadth, and one or more inches in thickness, according to the weight they are to carry. The edge rail is formed of pieces of cast or wrought iron (the latter is now generally preferred) with a ledge or flanch rising at right angles in the inner side of the rail. The flat rails are generally laid on pieces of timber called sleepers, and the edge rails on solid blocks of stone, from nine to twelve inches in thickness. The suspension rail consists of a line of vertical edge, elevated on posts; across this line the load is placed, like the panniers on the back of a horse, by a suitable contrivance for diminishing friction, and adjusting the weight so as it may be

equally important on both sides. As we have before observed, this subject belongs more properly to engineering than to agriculture, and therefore we shall confine ourselves to remarks, on subjects like this, as far as connected with, common country roads. (*Trans. Agric. Soc. vol. vi.*)

5787. In countries, the surfaces of which are rugged, or where it is difficult to obtain water for lockage, where the weight of the articles of the produce is great in comparison with their bulk, and where they are mostly to be conveyed from a higher to a lower level.—In these cases, Telford observes, iron railways are, in general, preferable to canal navigation.

5788. On a railway well constructed, and laid with a declivity of fifty-five feet in a mile, it is supposed that one horse will readily take down waggons containing from twelve to fifteen tons, and bring back the same waggons with four tons in them. This declivity, therefore, suits well, when the imports are only one fourth part of what is to be exported. If the empty waggons only are to be brought back, the declivity may be made greater or an additional horse applied on the returning journey will balance the increase of declivity. If the length of the railway were to be considered, it may it is supposed, without much inconvenience, be varied from being level to a declivity of one inch in a yard and by dividing the whole distance into separate stages, and providing the number of horses suitable for each portion of railway according to the distance and degree of declivity, the whole operation may be carried on with regularity and despatch.

5789. Railways may be laid out so as to suit the surface of very irregular countries, at a comparatively moderate expense. A railway may be constructed in a much more expeditious manner than a navigable canal, it may be introduced into many districts where canals are wholly inapplicable, and in case of any change in the working of mines, pits, or manufactories, the rails may be taken up, and laid down again in new situations, at no very great expense or trouble.

5790. The whole load to be drawn by one horse upon railways was at first put into one waggon, but now, when the load is so much augmented, it has been found eligible to divide it into many parts, so that no one waggon shall carry more than one or two tons by this method the weight is so divided, that the pressure is never so great upon one

point as to be in danger of too much crushing the road; the carriages can be made much more lumber and light in all their parts (*Ag. 573.*), and they are much more easily moved, and more manageable in all respects, than they otherwise would have been. And another advantage of this arrangement, which deserves to be particularly adverted to, is, that it admits of shunting the carriages, so as to leave a load, as it were, in parcels at different places where they may be required, without trouble or expense. Thus, when it comes to be fully understood and carried into practice, will be a convenience of inestimable value, a thing that has been always wanted, and never yet has been found, though it has been diligently sought for.

5791. Of the advantage of railways a striking proof is given by Anderson (*Recreations, &c.*), in the case of one formed by Wilkes near Loughborough. Its extent was about five miles, and it led from a coal-mine to a market. He found it so fully to answer his expectations after it was finished, that he communicated to the Society of Arts an account of some trials he had made of it, requesting that each of the members of that respectable institution as were desirous of information on that head would do him the honour to witness some experiments that he wished to make upon it for the information of the public. A committee of the members was accordingly deputed for that purpose, and before them he showed that a moderate-sized horse, of about twenty pounds value, could draw upon it with ease down hill (the descent being one foot in a hundred) thirty-two tons, and without much difficulty forty-three, and seven tons up hill, independent of the carriages. The doctor concludes from these facts, that upon a perfect level a horse could draw with ease from ten to twenty tons. It is observed that Wilkes's railway, on which the experiments were made, was, from local circumstances, laid upon wooden sleepers, and is not so perfect as those done upon stone. But it is added, that twenty tons constitute the load which such a horse could draw with ease, travelling at the usual waggon rate, in boats upon a canal; so that the number of horses required in this way will not be much, if at all, greater than on a canal. Certain advantages attach to this mode of conveyance, which do not so well apply to a canal, and *vice versa*; but it is not his intention to draw a parallel between these two modes of conveyance. Nobody can entertain any doubt, he thinks, about the utility of canals where they are easily practicable. He only wishes to point out this as an eligible mode of conveyance, where canals cannot be conveniently adopted.

3782. *In forming and constructing railways, the best line the country affords should be traced out, having regard to the direction of the carriage of articles, or trade to be expected; and if such trade be both ways in nearly equal quantities, a line as nearly horizontally level as possible should be chosen. If the trade is all in one direction, as is generally the case between mines and navigation, then the most desirable line is one with a gentle gradual descent, such as shall make it not greater labour for the horses employed to draw the loaded waggons down, than the empty ones back, and this will be found to be the case on a railway descending about one foot vertical in one hundred feet horizontal or, if the railway and carriages are of the very best construction, the descent vertical may be to the length horizontal as 1 to 80, where there is little or no upgate loading. In cases between mines and navigations, the descents will often be found greater than could be wished. On a railway on the improved plan, where the descent is more than as 1 to 80, six or eight waggons, loaded with thirty or forty hundred weight each, will have such a tendency to run downwards, as would require great labour of one horse to check and regulate, unless that tendency were checked by sledging some of the wheels. On such, and steeper roads, iron clippers are applied, one or more to a gang of waggons, as occasion may require. Each clipper being chained to the side of one of the waggons, and being put under the wheel, forms a sledge. Where the descent is very great, steep inclined planes, with machinery, may be adopted so as to render the other parts of the railway easy. On such inclined planes the descending loaded waggons being applied to raise the ascending empty, or partly loaded ones, the necessity of sledging the wheels is avoided, and the labour of the horse greatly reduced and lessened. (Fullon.)*

3793. *In order to obtain the desired levels, gentle descents, or steep inclined planes, and to avoid sharp turns and circuitous tracks, it will often be found prudent to cross valleys by bridges and embankments, and to cut through ridges of land and, in very rugged countries, short tunnels may sometimes be necessary. The line of railway being fixed, and the plans and sections by which the same is to be executed being settled, the ground for the whole must be formed and effectually drained. The breadth of the bed for a single railway should be, in general, four yards and for a double one six yards, exclusive of the fences, side drains, and ramparts.*

3794. *The bed of road being thus formed to the proper inclination, and the embankments and works thereof made firm, the surface must be covered with a bed of stones broken small, or good gravel, six inches in thickness or depth. On this bed must be laid the sleepers, or blocks to fasten the rails upon. These should be of stone, in all places where it can be obtained in blocks of sufficient size. They should be not less than eight, nor more than twelve, inches in thickness and of such breadth (circular square, or triangular) as shall make them 150 lbs. or 200 lbs. weight each. Their shape is not material, so as they have a flat bottom to rest upon, and a small portion of their upper surface level, to form a firm bed for the end of the rails. In the centre of each block should be drilled a hole, an inch and a half in diameter and six inches in depth, to receive an octagonal plug of dry oak five inches in length for it should not reach the bottom of the hole nor should it be larger than so as to put in easily and without much driving for if too tight fitted, it might, when wet, burst the stone. These plugs are each to receive an iron spike, or large nail, with a flat point and long head, adapted to fit the counter-sunk notches in the ends of two rails, and thereby to fasten them down in the proper position or situation in which they are to lie.*

3795. *With regard to the rails, they should be of the stoutest cast-iron, one yard in length each, formed with a flanch on the inner edge, about two inches and a half high at the ends, and three and a half in the centre; and shaped in the best manner to give strength to the rails, and keep the wheels in their track. The soles of the rails, for general purposes, should not, he thinks, be less than four inches broad; and the thickness proportioned to the work they are intended for. On railways for heavy burthens, great use, and long duration, the rails should be very stout, weighing 40 lbs., or in some cases nearly half a hundred weight, each. For railways of less consequence, less weight of metal will do, but it will not be prudent to use them of less than 30 lbs. weight each, in any situation exposed to breakage above ground. But it is observed that in mines, and other works under ground, where very small carriages only can be employed, very light rails are used, forming what are called tramroads, on a system introduced by Carr and these kinds of light railways have been much used above ground in Shropshire, and other counties where coals and other minerals are obtained.*

3796. *In laying the blocks and rails, great attention is required to make them firm. No earth or soft materials should be used between the blocks and the bed of small stones or gravel, on which the rails must all be fixed by an iron gauge, to keep the sides at a regular distance, or parallel to each other. The best width of road, for general purposes, is four feet two inches between the flanches of the rails the wheels of the carriages running in tracks about four feet six inches asunder. Rails of particular forms are necessary, where roads branch out from or intersect each other, and where*

carriage roads cross the railways; and, at crossings of the railways, great care is required to make them perfectly easy. The rails of the side forming the inner part of the curve should be fixed a little lower than the other and the rails should be set a little under the gauge, so as to bring the sides nearer together than in the straight parts: these deviations in level and width to be in proportion to the sharpness of the curve. The blocks and rails being fixed and spiked fast, nothing more remains to be done than to fill the horse-path, or space between the blocks, with good gravel, or other proper materials; a little of which must also be put on the outside of the blocks, to keep them in their proper places. This gravel should always be kept below the surface of the rails on which the wheels are to run, to keep the tracks of the wheels free from dirt and obstructions. The form of the rails must be such as will free them from dirt if the graveling is kept below their level.

5797 The formation of edge railways, on the middle or sides of public roads, has been recommended by Dr Anderson, Fultou, Edgeworth, Middleton, Stevenson, Mathews, Baird, and others. A flat railway, with the rail ten or twelve inches broad, we conceive, might be laid down along the sides of a road with advantage. It would require a rib below of sufficient strength to bear wagons of any weight. This strength would be communicated partly by the mass of material, but chiefly by the rib (fig. 574. a, a), resting on a bed of bricks or masonry below (b). Such a railroad might be used by any description of carriage,

574

light or heavy. But the best description of railroad for the sides of a highway is probably some of those formed of blocks of stone, already described. Stone railways of this sort appear to have been suggested by Le Large (*Machines Approuvées*, vol. iii.) in France, and afterwards by Mathews (*Committee Examinations*, May 1808.) in England, but they have never been fairly tried. The best specimen we have seen is in a street in Milan, where it is not so necessary, the whole breadth being very well paved.

## CHAP V

### Formation of Canals.

5798. Though the subject of canals is not included in that of agriculture, yet it is so intimately connected with territorial improvement, that it would be improper in a work of this description to pass it over. Canals of any extent are never the work of an individual: they are always formed by public bodies, constituted and empowered by public acts: but it is of importance to individuals to know the sort of effect which a canal passing through their property may have, both on its appearance and value: not merely as a medium of conveyance, but as a source of population, of water for irrigation or mills, or the use of stock, and even as an object of ornament. For this purpose we shall submit some remarks on the utility of canals, the choice of lines, the powers granted to canal companies, and the mode of execution.

#### SECT. I. Utility and Use of Navigable Canals.

5799. Good roads, canals, and navigable rivers, Dr Smith observes (*Wealth of Nations*, l. 229.), by diminishing the expense of carriage, put the remote parts of the country more nearly upon a level with those in the neighbourhood of large towns; and on that account they are the greatest of all improvements. They encourage the cultivation of the remote parts, which must always be the most extensive circle of the country. They are advantageous to towns, by breaking down the monopoly of the country in its neighbourhood; and they are advantageous to all parts of the country, for though they introduce some rival commodities into the old markets, they open many new markets to its produce. "All canals," says an intelligent writer on this subject (See *Philips's General History of Ireland Navigation*, Introd.), "may be considered as so many roads of a certain kind, on which one horse will draw as much as thirty harness on ordinary turnpike roads, or on which one man alone will transport as many goods as three men and eighteen horses nearly do on common roads. The public would be great gainers were they to lay out upon the making of every mile of a canal twenty times as much as they expend upon a mile of turnpike road; but a mile of canal is often made at a less expense than

the mile of transport, consequently there is a great inducement to multiply the number of canals."

3801. *General arguments in favour of canals* are supported by the rapidly improving and thriving state of the several cities, towns, and villages, and of the agriculture also, near to most of the canals of the kingdom: the immense number of acres of coal, iron, limestone, &c., and great works of every kind, to which they have been conducted, and to which a large portion of them owe their rise, are their best recommendation. In short, it may be concluded, that no canal can be completed and brought into use, but the inhabitants and the agriculture of the district will shortly feel great benefit from it, whatever may be the result to the proprietors.

3801. *The great advantages of canals as means of transport* result from the weight which may be moved along by a small power. The velocity with which loads can be drawn along a canal is confined within very narrow limits, owing, as Edgeworth has observed, to the nature of the resistance to which they are exposed. This resistance increasing in a geometrical proportion as the square of the velocity with which the moving body is impelled: whereas, on roads or railways, an increase of velocity requires only an arithmetical increase of power. Or, in other words, to draw a boat with ten times a given velocity would require a hundred times as much power as was requisite to draw it with that given velocity: whereas, to draw a carriage on a road or railway with ten times a given velocity would require only ten times the given power. For this reason, however advantageous canals may have been found, for transporting heavy loads, they will be found upon trial inferior to roads in promoting expedition.

3802. *Canals appear to have been first made in Egypt*. Though less attended to by the Romans than roads, yet they formed some in this country near Lincoln and Peterborough.

3803. *Canals is remarkable for its canals*, and there are said to be many in Hindostan, though we believe they are principally for the purpose of irrigation. In Russia there are some, and several in Sweden; one or two in Denmark, some in Germany, and a great many in Holland. The canal of Burgundy in France was commenced under Henry IV. and that of Languedoc finished by Riquet, the Minister of France, under Louis XIV. Some attempts have been made to form canals in the jolly country of Spain, and a great many excellent ones are executed in America.

3804. *Navigable canals in Britain* took their rise between 1735 and 1760, by the Stanley Brook Company in Lancashire, but the great impulse was given by the duke of Bridgewater about 1767, when he first commenced, under the direction of Brindley the canal between his coal-works at Worsley and Salford. The duke of Bridgewater has, in consequence, not improperly been called the father of canals in England: while his engineer Brindley by his masterly performances on the duke of Bridgewater's canal altered and extended as the scheme thereof was by the three subsequent acts of parliament, has secured to himself and will, it should seem, from a comparison of the great features and magnitude of execution in this the first canal, with most others in this country, even of the latest construction, long continue to hold that rank among the English engineers, to which Riquet seems entitled among foreigners.

3805. *Since the duke of Bridgewater's time* the extension of canals in the British Isles has been rapid. A number of scientific engineers have arisen, of whom we need only mention Smeaton, Rennie, and Telford, and point to the Caledonian canal.

#### BOOK II. Of discovering the most eligible Route for a Line of Canal.

3806. *The first object when the idea of a canal is determined on* by a few landed proprietors, is the choice of a skilful and experienced engineer. Such an artist should undoubtedly possess a considerable degree of mathematical knowledge. Calculations, of which some are of the most abstruse and laborious kind, will frequently occur; and he should, therefore, be well acquainted with the principles on which all calculations are founded, and by which they are to be rightly applied in practice. An engineer should also have studied the elements of most or all of the sciences immediately connected with his profession and he should particularly excel in an acquaintance with the various branches of mechanics, both theoretical and practical. His knowledge should comprehend whatever has been written or done by other engineers and he should have information in every department of his business, from an accurate examination of the most considerable works that have been executed, under all the various circumstances that are likely to occur. It is necessary that he should be a ready and correct, if not a finished, draughtsman. He should also be conversant with the general principles of trade and commerce, with the various operations and improvements in agriculture with the interests and connection of the different owners and occupiers of land, houses, mills, &c. and with all the general laws and decisions of courts pertaining to the objects connected with his profession. By an extensive acquaintance with the disposition, inclination, and thickness of the various strata which compose the soil or land of the British Islands, he will be able to avoid many errors incident to those who are destitute of this knowledge. As the last, though not the least, of these qualifications of an engineer which we shall enumerate, he should be a man of strict integrity.

3807. *A proper engineer being fixed upon*, the adventurers should not tie him down too closely by restrictions as to time, but allow him leisure to consider, digest, and revise, again and again, the different projects and ways, which will, in most instances, naturally present themselves to him in an extensive and thorough investigation. The engineer should be allowed to choose and employ the most competent assistants, and to call in and occasionally to consult the opinions of eminent or practical men, as land-surveyors, agents of the neighbouring landed property the principal and most expert commercial men of the district who are best acquainted with its trade and wants, any eminent miners, &c. &c. and such men the engineer should be instructed liberally and at once, to remunerate for their services and intelligence. From the beginning of any minute survey or system of levelling, the engineer ought to visit all the objects within the district under consideration, and endeavour to make a just estimate and preserve remembrance of them as of the trade and importance of all the towns likely to be affected by the undertaking, of all mines of coal, iron, &c. quarries of limestone, freestone, slate, &c. or the situation where such can be found, of all the manufactures of heavy and cumbersome goods, and other extensive works, and generally of every thing likely to furnish *tonnage* for a canal. The most eligible route for a canal being settled in the engineer's mind, he will then proceed to make a rough calculation of the quantity of goods of such kind which may be expected to pass upon the line in a given time; he will also

supplies all the lands and towns with which the proposed canal is to connect, and ascertain the widths and depths thereof, the state of their lands, and of the various property surrounding them.

3808. The direction, number, and kind of locks or locks or inclined planes, length of locks, &c. may now be determined on, and how far bridges or embankments or locks may be connected with the main line. Many engineers, and especially F. Smith, have recently advocated the formation of small canals. On this subject, Mr. Smith, in a recent publication, writes, observing, "that the system of small canals is particularly eligible in all countries where distances, soil, town, &c. and other numerous articles, not liable to damage from being wet, or not liable to be washed away, are the objects chiefly to be attended to; and where the fertility of the country runs immediately in the course of the canal, which will generally be the case along the sides of mountains, at an elevation above the regular ground at their feet. In these situations, the great falls or inclined planes may be made at the foot of the dams, so that the upper levels may branch up both the sides, and thus give the most extended communication. A situation suited for these small canals will often be found in countries that are not absolutely mountainous, but where the ground regularly declines according to the rules or large rivers."

3809. A rough section of the proposed line will enable the engineer to see the places of the heights, and heights of the various mountains, or ranges of high land, that are to be passed, and whether any two or more adjacent ones can be connected by a long summit level, without demanding any considerable turn or point of transit, which will diminish the difficulties of supplying the canal with water. As every such junction of summits preserves the water of two lockages, besides presenting to many more points at which the canal can be supplied with water from springs and rivulets above its level, or where, in less favourable situations, the water can be collected in a lower level, to be pumped up. From one end of the proposed summit level it will be right now to proceed with the survey, tracing the level accurately, and marking the same by pegs or stakes, that will last for some time, and be known by the surveyor who is to follow and make a plan of the line. The levels being frequently transferred to what are called bench marks, upon the trunk of a tree, a large rock, or a building, the same need not be repeated at the first, or survey book, that they may be readily found for years afterwards. We suppose the engineer, by this time, to have settled the rise that each lock should have, according to the dimensions adopted for the canal, the probable supply of water on the summit, and other circumstances. The summit level will be traced as above, till the proper place occurs for making a fall of two or more locks, at about 100 yards, or a little more from each other. And the places of the two falls being marked, the level is again to be pursued and traced from the bottom of them, and marked out as before, till the opportunity occurs for another pair or more of locks, or till some obstacle, as a gentleman's park, houses, gardens, orchards, mills, roads, &c. present themselves at a distance, when it will be proper after transferring the level arrived at to a proper and permanent mark, to proceed forwards, and to examine and well consider the different ways and levels, if more than one present themselves, by which the obstacle can be passed. From the most confined part of the course for the canal, away to the obstacle, it will be right to level back, till the former work is met, and to determine the most eligible mode of bringing the two levels together upon the principles before stated. If they can be applied, either by adding another lock, or taking one from any of the sets which had been before marked out, as occasion may require, and marking out the new levels thereby occasioned. The line between the summit and the first obstacle, or confined part of the course, being thus adjusted, a new point of departure is to be taken from such obstacle, and the level pursued as before, till the fall for a pair or more locks can be gained, at the proper distance from each other. In this way the patience, perseverance, and abilities of the engineer must be exercised, until a practicable line of some length is obtained, and sketched out when the assistant land-surveyor must follow and make a correct and particular plan of the line of the several proposed locks, embankments, tunnels, &c. upon the same, and of the several fields, or pieces of land through which it passes, or that come within 100 or 150 yards of it in any part. It will likewise be the business of the surveyor to ascertain, with the utmost care, the boundary of every parish and town dike; what country enters in so. The proper names of the owners and occupiers of every piece of land in such, however small, upon or within that distance of the line, with reference to the same upon his plan, and to describe correctly all public and private roads and paths that cross or intersect the line, and to add from what places they lead. The course of all brooks or streams of water, and particularly such as lead in, and contribute to the supply of, any mill. The situation of the houses and towns upon the line, or within some miles of it, should also be determined. The nearer they are the greater accuracy will be necessary. A complete plan of the line, and all the proposed collateral cuts, feeders, reservoirs, &c. being finished, the engineer will enter on a most careful revision of the whole scheme with this plan in his hand, on which all the places where sluices or drains will be required are to be marked, as also the proper places for the bridges, and the necessary alterations of the roads and paths, which will be cut off by the canal, so that the public may not be inconvenienced and turned long distances round about, and still, that as few bridges as possible, and those in the least expensive places, may be erected. In some instances new channels will require to be cut for brooks and water-courses, to a considerable extent, in order to save culverts, or bring them to the most desirable spots. For proper security against accidental errors, the whole of the line being should now be gone over again, and the several bench marks compared, and renewed with the utmost care by the engineer's assistants, while he is proceeding with the necessary surveys and calculations for an estimate of the whole expense of the undertaking.

3810. The supply of a canal must never, in a great number of instances, occasion no inconsiderable share of the whole expense, either in the first cost of mills or streams of water, in land for and labour in constructing, reservoirs, engines to pump water, &c. or annually ever afterwards, in the fuel for and repairing of engines, hire of water from mills in dry seasons, &c. this subject should, therefore, employ the most sedulous attention of the engineer to make the most economical use of what streams he finds, to prevent other supplies of water at the least expense, and above all, to secure abundance. The dimensions and height of the locks, and breadth of the canal, being settled, an accurate calculation should be made of the quantity of water required to fill a lock, and with the largest probable number of boats that will pass in a day of the quantity required daily in every part of the canal, and, with a due allowance for the evaporation, from the surface of the whole canal and its reservoirs, and for the seepage that will take place into the banks, however well they are constructed, will show the number of locks full of water that will be required, from the different courses.

3811. In estimating the expense of all such works, it will be necessary to have the lengths and solid contents of the several embankments, and the distance from which the stuff or soil must be fetched for the same, the lengths and dimensions of all the deep cuttings, and the distance to which the stuff must be removed, the lengths of the tunnels, and number and depths of the several shafts or tunnel pits the lengths or headings of workings that will be wanted to drain the tunnelling work. These, and all the great variety of other works, some of which we have already mentioned and others we shall have occasion to mention in the sequel, being particularly stated, and prices affixed to each species of work and kind of material (which prices ought not to be below the current prices of the best articles at the time, and due allowance should also be made for the advance of prices which will take place during the progress of the work), the total probable expense, with a due allowance for contingencies, will be thus obtained, on which

the engineer will prepare his general report and estimate, to be laid, with the plan, before a meeting of the adventurers or proposed proprietors.

SECT. III. Powers granted to Canal Companies by Government.

3812. *As a canal must pass through a great variety of private property, and necessarily affect different individuals in very opposite ways, considerable powers are requisite to carry it into execution. The first steps to attain these are the appointment of a solicitor, and an application to parliament for an act of incorporation and regulation.*

3813. *A canal bill contains numerous clauses, but the following may be considered the most general heads:—*

*Regulations as to valuing money by shares or otherwise.*

*Election of committees, and general meetings of proprietors.*

*Encroachments relative to purchasing lands, &c.*

*Powers for erecting wharfs, and enforcing certain equitable rates of wharfrage.*

*Tolls, or rates of tonnage, with exemptions, if any.*

*Fixing mile-stones, for regulating distances and tonnage.*

*Removing the surface-soil, and clamping it, for the purpose of being again laid on the surface of the exterior banks of the canal; or for other purposes.*

*Forming watering places for cattle or irrigation.*

*Regulations as to mills, &c.*

*Power to make by-laws.*

*Form of surveying land to the canal company.*

*Regulations as to depositing plans of the canal, and making variations from them, &c.*

3814. *The act of parliament for a canal being passed, and therein the time and place for the first meeting of the subscribers or proprietors thereof being fixed; the first business of such meeting will be the election of a general committee of management, consisting of the most independent, respectable, and generally informed persons among the proprietors. The committee of management will then proceed to elect a chairman and subordinate officers, to fix upon their place of meeting, and to arrange the order of their business.*

3815. *A resident engineer and land-surveyor and valuer should now be fixed on, and probably also a local or select committee auditors of accounts will be appointed, and salaries determined. The chief engineer will now revise the line, and divide it into different parts, assigning names to each for convenient reference. Of these distinct parts, or divisions, a separate account of the expenses should be strictly kept by the resident engineer—the overseers, or counters, as they are generally called: that the engineer is to recommend or employ upon the works: and by the office clerks, in a ledger with proper heads for each length of canal set of locks, tunnel, embankment, deep cutting, reservoir, aqueduct, or other great work, that may form a separate division: such particular and divided accounts of the works will prove of the most essential service to the committee, and to all others concerned, in informing and maturing their judgment on the actual or probable expense of every different kind of work: and will enable the committee to explain to the proprietors how great, and sometimes unavoidable, as well as unexpected, expenses may be incurred.*

3816. *Such lands as are wanted should now be treated for by the land-surveyor, and the purchase and conveyance concluded with the approbation of the committee: and the aid of the solicitor with or without the aid of the sheriff and a jury as the case may require. In general, the ground for reservoirs and locks ought to be the first purchased, to permit the embankments and masonry to be proceeded with.*

SECT. IV. Execution of the Works.

3817. *The first operation of execution is the setting out of the work by the resident engineer and surveyor. He will accurately trace and indicate the levels of each pound or level reach of the canal, marking them with stakes, and comparing his work with the bench marks, he will also make two or more of the men who assist him perfectly acquainted with the position of the stakes, to provide against their derangement by cattle or from other causes.*

3818. *The calculations for excavation form the next part of execution. The great desideratum in canal-digging is, that the stuff dug from one part of the work shall, with the least labour of moving, exactly supply or form the banks that are to be raised in another, so that, on the completion of the work, no spoil banks, or banks of useless soil, shall remain, nor any ground be unnecessarily rendered useless by excavations or pits.*

3819. *Five different cases will be found frequently to occur in the cutting or forming of a canal. In each case the towing-bank (fig. 575. a) is wider than the off-bank (b);*

and, in all, the sides slope one foot and a half for one foot in depth, that being found the least slope which can be given.

*3821. Where there is deep cutting on one side (c), or both (d, e), a bench or berm (f, g) is provided to receive and prevent the loose earth that may slide down from the upper bank down during desiccation. The bench is usually made one foot higher than the water is intended to stand in them.*

*3822. In deep cutting (figs. 575 a, b), the height of the canal should be so contrived, that in any cross section the sum of the areas of the inside banks (a, b) should just equal that of the area of the nucleus of excavation (c).*

*3823. In side-hill ground (figs. 576 a, and fig. 576 f), the same object may be attained with a little more calculation; and in all other cases (g, h), the engineer will show the perfection of his skill in so conducting*

576

the line, that every embankment shall have deep cutting at both, or at least at one of its ends, to furnish the extra stuff with least expense in moving it; in like manner, every deep cutting (d, e) should have embankments at one or both of its ends, to receive the extra stuff.

**3823.** Before cutting out the lock-spot, or small trench between the several slope holes, as a guide to the men who are to dig the engineer ought to cause holes to be dug in the line of the canal, near every second or third level peg, or oftener if the soil be variable, in order to prove the soil to a greater depth, by two or three feet, than the cutting of the canal is to extend; and each of these the engineer ought carefully to inspect, in order to determine what puddling or lining will be necessary, and what will be the difficulties of digging, owing to the hardness of the stuff, or to water that must be pumped out, &c., all which circumstances, as well as the extra distances that any part of the stuff may require to be moved, must be well considered before the work can be let to the contractors.

**3824.** The puddling or lining of the canal, to make it hold water, is a matter of the greatest importance, and we shall consider five cases that are likely to occur or present themselves in the search into the soil that is to be dug, by sinking holes as above mentioned. The first case we suppose to be that in which the whole is clay loam, or other water-tight stuff all soils that will hold water, and not let it soak or percolate freely through them, are called water-tight. Our second case is that in which the whole cutting will be in sand, gravel, loose or open rock, or any other matters that will let water easily through them, and such are called porous soils or stuff. The third case, we suppose to have a thin stratum of water-tight stuff on the surface, and to have porous stuff for a considerable depth below. The fourth case may have porous stuff near the surface, and water-tight stuff at the bottom of the canal. The fifth case is that where water-tight stuff appears on the surface and below this a stratum of porous stuff, but having again water-tight stuff at no great distance below the intended bottom of the canal. The new-raised banks are always to be considered as porous stuff, as, indeed, they will always prove at first, and in a great portion of soils they would ever remain so, unless either puddling or lining were applied, all ground that has been dug or disturbed, must also be considered as porous. It should also be remarked, that any kind of soil which is perforated much by worms or other insects, should, in canal-digging, be considered as porous stuff.

**3825.** Puddle is not, as some have attempted to describe it, a kind of thin earth mortar, spread on places intended to be secured, and suffered to be quite dry before another coat of it is applied; but it is a mass of earth reduced to a semifluid state by working and churning it about with a spade, while water just in the proper quantity is applied until the mass is rendered homogeneous, and so much condensed that water afterwards cannot pass through it, or but very slowly.

*3826. The best puddling stuff is either a lightish loam, with a mixture of coarse sand or fine gravel in it; very strong clay is unfit for it, on account of the great quantity of water which it will hold, and its disposition to shrink and crack as this dries; vegetable mould, or top soil, is very improper on account of the roots and other matters liable to decay and leave cavities in it; but more on account of the temptation that these afford to worms and moles to work into it, in search of their food. Where puddling stuff is not to be met with, considering a due mixture of sharp sand, or rough small gravel stones, it is not supposed to procure such to mix with the loam, to prevent moles and rats from working in it; but no stones larger than about the size of musket bullets ought to be admitted.*

**3827.** That the principal operation of puddling consists in consolidating the mass, is evident from the great condensation that takes place; it is not an uncommon case, where a ditch is dug, apparently in firm soil, that though great quantities of water are added during the operation, yet the soil which has been dug out will not, when properly worked as puddle, sink up more than two thirds of the ditch. It should even, when that puddle is condensed by that quantity capable of holding a certain proportion of water with great closeness, and that it is more fit to hold than transmit water. It is so far from true, that puddle ought to be suffered to get quite dry that it entirely soaks when by exposure to the air it is too much dried; and many canals which have remained unlined with water during a summer after their puddling or lining has been done, have thereby become very leaky, owing to the cracks in the puddle-skin or lining. One of the best cases of an engine, when beginning to cut a canal, is to discover whether good puddling stuff is available; and, if it is not, it must be diligently sought for, and carefully wheeled out or reserved wherever any is found in the digging; or, perhaps, it must be procured at considerable distances from the line, and brought to it in carts. It has happened in some stone-brush or loose rocky soils, that all puddling stuff for several miles of the line required to be brought to it. But even this expense, tedious as it may be, ought not to induce the trusting of them, who have left miles of such banks without puddling, and have made a wider canal, but one which no stream of water that is to be procured can keep full in the summer months. It is usual to cause not to insert a clause, for the security of the landowners, to require the company to secure all the banks that need it to be secured by puddling, to prevent damage to the land below by leakage; and it would have been well for all parties, in many instances, if this clause had been enforced.

3828. *If we compare our first, fourth, and fifth cases (3824), we shall find in all of them a water-tight system, as the basin and the piers in these cases is to make a wall of puddle, called a puddle-ditch, or puddle-gutter, within the bank of the canal: these puddle-gutters are usually about three feet wide, and should enter each a foot into the water-tight shaft on which they are always to be kept; and they should be carried up as the work proceeds, to the height of the top water-line, or a few inches higher. Our second and third cases (3825) evidently will not admit of the above mode, because we have no water-tight structure on which to begin a puddle-gutter as a bottom: in these cases, therefore, it is usual to supply a lining of puddle to the sides and bottom of the canal.*

3829. *History of puddling.* It appears that the Dutch have been in the habit of making mud ditches to secure the banks of their canals and embankments, from time immemorial and that operations similar to our puddling have been long known on the Continent, but it is not clear at what period it was introduced into this country. We think that the fens in Cambridgeshire and Lincolnshire, in which so many works have at different times been executed by Dutchmen, are the most likely places in which to search for early evidence of its use. We cannot think that Brindley was the first who ever used it in this country although we might admit that the Bridgewater canal was the first in which it was systematically employed as at the present day.

3830. *Adjustment of materials.* Canals set out with the care that we have recommended, will always have the proper quantity of stuff to allow for the settlement of the banks since the united sections of the loose banks will always equal the section of excavation in the same settled or consolidated state in which it was before the digging commenced. The slopes of made banks, it is to be observed, on account of their settling, should be steeper in the first instance than they are ultimately required to be.

3831. *The letting of the cutting of certain lengths of the canal to contractors, who will employ a number of navigators under them, in digging and puddling the canal, is the next business.*

3832. *It is usual to let the work at a certain price per cubic yard of digging and to pay for the puddling or lining either at a certain price per cubic yard or per yard run of the canal. The engineer ought to inform himself thoroughly of the difficulties and facilities which attend the work he is about to let, and to draw up a short but explicit contract to be signed by the contractor. The price allowed ought to be fair and liberal, according to the circumstances, so that the contractor may have no pretence on account of low prices, to slight his work particularly the puddling and they ought in every instance to be strictly looked after, and made to enter and re-enter immediately any work that may be found improperly performed. We recommend it to the engineer to keep a strict account, by means of his own men or counters, of the time of all the men employed upon the works, distinguishing particularly the number upon each work, and whether employed under the company by the day or upon the work let to contractors. These particulars are most essential towards knowing what money ought to be advanced to the contractor during the progress of his job, and towards informing and mastering the judgment of the engineer, with regard to the length of time that a certain number of men will be in performing any future work he may have to direct. A calculation should also be made of the day work in every instance, and compared with the contract price, by which alone a correct judgment can be formed of the proper prices at which work ought afterwards to be let, so that the labourers may receive wages proportionate to their exertions, and the contractor be amply paid for his time, skill, and superintendence and yet economy and the interest of the company be duly consulted.*

3833. *Barrows and wheeling plants, boring-blocks and other implements, are generally found by the company and it is usual to consider twenty to twenty five yards a stage of wheeling and to fix a price per cubic yard according to the number of stages that the soil is to be moved. Where this distance exceeds 100 yards it will rarely be eligible to perform it by wheel barrows, therefore runs of plank with an easy descent, if the same be practicable should be laid, for large two-wheeled barrows or trucks to be used thereon.*

3834. *Where the line of a canal is to cross an extensive stratum of valuable brick earth or one of good gravel for making roads it will often be advisable, especially if the line can be thereby rendered more direct, when setting out the canal, to cut pretty deep into such materials, and even quite through the gravel, if the same be practicable for although considerable expense will in the first instance be incurred in digging and in damage done to good banks, yet such materials as good brick earth and gravel will, in almost every instance, find a market as soon as the canal is opened. Such a situation may prove of essential service to the trade of the canal by enabling the adjoining proprietors to work the whole thickness of their brick earth, gravel, or other useful matters, with but little detriment to the surface of the ground, and without being annoyed by water thus the canal, instead of losing water by preserving a high level through porous stuff, would, it is probable, catch so very considerable quantities. In districts where stone and gravel for making and repairing roads are scarce, it will be proper to pay the labourers certain rates per cubic yard for all the stones or gravel that may be collected by them during the work, and stacked in proper places. These will form resources for making the towing-path and for making good the landing or ascent to the several bridges and the several pieces of new road that the engineer will have to form next to the canal bridges. The lock banks, and all wharfs and landing places, should also be covered with good gravel, to render them safe and convenient for use. If good gravel can in places be interstruck in deep cuttings, much of the above expense, as well as that of cartage may be saved, by an early use of dirt boats in the bottom of the canal.*

3835. *How important and various the duties of the resident engineers are, must have struck every reader; but it would be much more apparent, could we enter into the subject of reservoirs, feeders, aqueducts, embankments, culverts, safety gates, weirs, tunnels, deep cuttings, locks, substitutes for locks, inclined planes, railways, bridges, towing-paths, fences, drains, boats, towing or moving boats and trams, cranes and implements but these, as less important for our purpose, we must leave the reader to study in the works of Phillips, Fulton, Chapman, Plymley, Badeslade, Kenderly, Anderson, Telford, and from the article Canal, in the three principal Encyclopedias.*

3036. *Consistent with the laying out of roads and canals, is the establishment of different forms of manufacturing industry.* The forced introduction of these will be attended with little benefit; but where the natural and political circumstances are favourable, the improvement is of the greatest consequence, by retarding on the same estate, as it were, the profits of the grower, the manufacturer, and to a certain extent of the consumer.

3037. *The establishment of mills and manufactories to be impelled by water, necessarily depends on the abundance and situation of that material; and it should be well considered beforehand, whether the water might not be as well employed in irrigation, or how far irrigation will be hindered by the establishment of a mill.* In the state of society in which water-corn-mills were first erected, they were doubtless considered as blessings to the country. There were then no flour manufactories, and it was more convenient for the inhabitants to carry their corn to a neighbouring mill, than to grind it less effectually, by hand, at home. Hence, the privileges and immunities of manorial mills. To secure so great a comfort, every tenant of a manor would willingly agree to send his corn to be ground at the lord's mill; and, perhaps, was further obliged to stipulate to pay toll for the whole of his growth; though it were sent out of the manor unground.

3038. *In Scotland, this impost, and now abroad, custom was only lately given up.* till when no farmer dared to send his corn to market, until he had delivered a proportional quantity to the proprietor or the occupier of the mill to which he was tithed, or had previously stipulated to pay him thirings for what he might send away; this arbitrary regulation operating, like tithes, to decrease the growth of corn.

3039. *In England and Ireland, however, no restriction of this sort at present exists.* but, in the remote parts of the north of England, there are mills which claim (or lately claimed) the exclusive right of grinding the whole of the corn which the inhabitants of the respective parishes or manors prepared to be ground for their own use, suffering none to be sent out of the parish for the purpose of grinding. In the more western counties, where grist mills are still the school of parochial scandal, something of this sort remains, and is scarcely preserved in modern leases: but, in the kingdom at large, grist mills are now going fast into disuse. Even working people purchase flour instead of corn, and, whether in a private or a public light, this is an eligible practice. They can purchase a sort which is suited to their circumstances, and they know the quality and the quantity of what they carry home: whereas, in the proverbial vicinity of grist-milliers, they have no certainty as to either. Besides, in a flour mill there is no waste; every particle may be said to be converted to its proper use.

3040. *A valuable property belonging to modern flour manufactories, is their not requiring every break and rivallet of the kingdom to work them.* In Norfolk, a great share of the wheat grown in that county is manufactured into flour by the means of windmills: and such are modern inventions, that neither wind nor water is any longer necessary to the due manufacture of flour: the steam engine affording if not the most eligible, at least the most constant and equal power.

3041. *The most eligible kinds of water-mills are, the tide-mill and the current-mill: the former placed in creeks, lagoons, bays, estuaries, or tide rivers; and the latter in the current of a river.* There are many situations, Marshall observes, in which these species of mills may be erected with profit to proprietors, and the community: and without any injury to the landed property, or the agricultural produce of the country. He is of opinion that numerous river-mills existing in different parts of the country are unnecessary to the present state of society.

3042. *Grist-mills may be still required in some remote situations:* but, seeing the number of flour-mills which are now dispersed over almost every part of the kingdom, seeing also the present facility of carriage by land and water and seeing, at the same time, the serious injuries which river-mills entail on agriculture, Marshall recommends land-proprietors to reduce their number as fast as local circumstances will allow.

3043. *The inducement to establish manufactories depends on a variety of circumstances, as well as on a supply of water.* Among these may be mentioned the price of labour, convenience for carriage, export or import, existence of the raw material at or near the spot, as in the case of iron-works, potteries, &c. In England, while the poor laws exist, the establishment of any concern that brings together a large mass of population will always be attended with a considerable risk to land-owners; though it is a certain mode, in the first instance, of raising the price of land, and giving a general stimulus to every description of industry.

3044. *A populous manufactory, even while it flourishes, according to Marshall, operates much more evilly in an agricultural district by propagating habits of extravagance and immorality among the lower order of peasantry, as well as by rendering them labourers and servants dissatisfied with their condition in life, and the wages it furnishes, and the higher wages it pays, the more mischievous it becomes in this respect. Landlords bear a mutual value in proportion to the rate of living in the district in which they live, so that while a temporary advantage is reaped, by an increased price of market produce, the foundation of a permanent disadvantage is laid; and, whenever the manufactory declines, the fruits of its neighbourhood have not only its vices and extravagances settled upon them, but have the vicious, extravagant, helpless manufactory themselves to maintain. The accumulation of evils however belongs particularly to that description of manufactory which draws numbers together in one place, where closeness of the body and the mind are jointly promoted; and where no other means of support is taught than that of some particular branch or branches of manufactory. But all these evils, belonging to the first introduction of manufactory on a great scale, will be cured with the progress of education and refinement among the operative manufactorymen; it is already improved in comparison with what it was in Marshall's time.*

3045. *Cottages.* Whenever cottages for any class of men are built, whether singly or congregated, they ought never to be without an eighth or a fourth of an acre of garden ground. It is observed in the *The Code of Agriculture*, that "where a labourer or country tradesman has only a cottage to protect him from the inclemency of the weather, he cannot have the same attachment to his dwelling, as if he had some land annexed to it; nor is such a state of the labourer so beneficial to the community. When a labourer has a garden, his children learn to dig and weed, and in that measure some of their

time is employed in useful industry. If he is possessed of a cow, they are taught early in life the necessity of taking care of cattle, and acquire some knowledge of their treatment. But where there is neither a garden to cultivate, nor any cows kept, they are not likely to acquire either industrious or honest habits. So strongly were these ideas formerly prevalent, that, by the 45d of Elizabeth, no cottage could be built on any waste without having four acres attached to it. This is in general too much. If the quantity were reduced to half an acre for a garden, and if no person could gain a settlement who was not a native, or, if a stranger, who did not fairly rent in the same parish a house and land worth twenty, instead of ten pounds per annum, both the poor and the public would thence derive very essential benefit."

3843. *The most advantageous system for keeping a cottage cow is that adopted in grazing districts, where a cottager has a sufficient quantity of enclosed land in grass, to enable him to keep one or two cows both summer and winter, grazing the one half, and mowing the other alternately. Nothing tends more materially to teach the poor honesty than allowing them to have property. Feeding now honestly they would deprive all indigence upon it, they are less likely to make depredations upon that of others; and this will produce more honesty among them than the best delivered precepts can effect. By the cultivation of a small spot of land, a cottager not only acquires ideas of property, but is enabled to supply himself with that variety of food, as fresh vegetables in summer and roots in winter, which comfort and health require. If he should fortunately be able to keep bees in his garden, and if his surplus produce should also enable him to rear, and still more to fatten, a hog, his situation would be much improved. But if, in addition to all these advantages, he can keep a cow the industrious cottager cannot be placed in a more comfortable situation. Goats have recently been recommended (*British Farmer's Magazine* vol. iii.) as a substitute for a cow as being more easily kept, costing less at first, and producing milk the greater part of the year. The chief difficulty of introducing them is the want of sufficient enclosures, as no animal is more inclined to straggle vegetation of any kind. Some useful hints on the subject of cottagers, and the means by which they may be enabled to keep a cow will be found in Cobbett's *Cottage Economy* though his statements are in many cases highly exaggerated.*

3847. *Cottages and villages necessarily result from manufactures, as well as from extensive mines, quarries, or harbours. A few cottages will necessarily be scattered over every estate, to supply day labourers and some description of country tradesmen. Villages are seldom, in modern times created by an agricultural population, it being found so much more convenient for every farm to have a certain number of cottages attached to it.*

3848. *Villages may be created any where, by giving extraordinary encouragement to the first settlers but unless there be a local demand for their labour, or they can engage in some manufacture, the want of comfortable subsistence will soon throw the whole into a state of decay. Fishing villages, and such as are established at coal and lime works, are perhaps the most thriving and permanent in the kingdom. Some fine examples of fishing villages, recently established, occur on the Marquess of Stafford's estates in Sutherland.*

3849. *In forming the plan of a town or village the first thing, if there is a river or other means of communication by water is to fix on a proper situation for a quay or harbour and next, at no great distance from it, on an open space as a market. Round the latter ought to be arranged the public buildings, as the post-office, excise or custom-house, police-office, the principal inn and the principal shops. Near the harbour ought to be placed the warehouses and other depositories for goods; in a retired part of the town the school and out of town on an eminence (if convenient) the church and the cemetery or garden of burial. There ought to be a field or open space, as a public recreation ground for children, volubins or troops exercising, mews, washing and drying clothes on certain days, &c. Public assemblies ought to be formed in a retired and concealed spot, so should public necessaries. Proper pipes, wells, or other sources of good water, with the requisite sewers and drainage should also be provided. Buckets, to be used in case of fire, ought to be kept at the market-house.*

3528. The village of *St. John's* on the *Amur*, in *Transbaikalia* (*Fig. 573*), was begun in 1832, by *Gen. Durno*, and is thus described by him in the survey of the country:—"It is situated at a point of the river which affords safe and power capable of carrying any weight of machinery; and I have had it in view to give encouragement to manufacturing, to whom such a situation is an important object. A woollen manufactory [a] upon a large scale, and the most approved plan, has been established there for ten years, and is gradually increasing its machinery. In this village there are already in the course of this time, about two hundred and fifty industrious inhabitants, and it has every appearance of a further rapid increase. On the opposite side of the river a situation is fixed on for corn-mills (b), where a complete set has been built upon the best construction, including wheat and barley mills. Half of the water there is reserved for any other works, and is likely to be let for a mill for dressing and for spinning flax, and for machinery required in bleaching, there being at the foot of the mill-race a horse of six acres (c), well calculated for a bleach field; and I propose to let part of it for such a manufactory."

3529. "The lots for building and gardens in the village, each consisting of from nine to ten fathoms of ground, are granted in perpetuity at the rate of six pounds the English acre, either upon leases for 999 years, or for 99 years, as the settlers choose; the former being generally preferred, as being the holding or title attended with least expense. This rent would be no object when the waste of ground in streets and enclosures is considered; but the great advantage to be derived from such an establishment is, the increased value that lands acquire from having a number of industrious people settled in the heart of an estate. Each person who takes a house-plot is obliged to build with stone and lime, according to a regular plan; and a common entry is left between every two lots for access to their offices, which are built immediately behind their houses; and the whole of the buildings are covered with slate. The settlers are also bound to make a common sewer through their property when required; to pave ten feet in front of their houses, between them and the street; and to pay at the rate of a penny per fall yearly according to the extent of their lots, to form a fund for keeping the streets and roads in repair and for making small improvements. No person is allowed to sell liquor of any kind without my permission; nor can any shop or chandlery, tannery or other work, that might be considered as a nuisance, be set up or built, unless in places allotted for these purposes, and to prevent all interference on the part of the farmers, I reserve to myself full liberty to make such alterations as may appear to me or my successors to be proper in the plan of the village. These regulations are the best security against having vagabonds in such a place, as none but industrious people can afford to build or rent such houses."

3530. A new village on the *Amur* was formed by *Sir Lawrence Palk*, in the northernmost part of *Turkey*. A new pier projected south-westwardly from the eastern shore, affords complete protection to shipping from the south-east winds. The regularity of the buildings lately raised for the accommodation of company resorting thither for the convenience of sea-bathing, adds neatness and beauty to the wild and picturesque scenery of its natural situation; and, from the size of the vessels the harbour is now capable of protecting whilst they receive and discharge their cargoes, there are well-grounded expectations that this place will become of some maritime consequence on a future day. A plan of this sea-port (*Fig. 574*).

574

is given in the *Dover Survey*, and is described as containing a pier (1) quay (2) harbour (3) warehouses (4) inn and garden (5) stables (6) strand (7) cove for building ships and lumber yard (8) beacon (9) cove for bathing-vestments (10) new carriage-way to the park (11) terrace (12) the park (13) plantation (14) road to *Turrow* (15) road from *Newton*, &c. (16) meadows (17) circus in the park (18).

## CHAP. VII.

### Of Mines, Quarries, Fossils, and Metalliferous Bodies.

3531. *Against mines*, as a species of property, considerable prejudice has long existed, from the variation of their produce, and the uncertainty of their extent and duration. Modern discoveries in geology, however, have thrown great light on the subject of mining, and introduced into the art a degree of certainty not before contemplated. In proof of

this, we may instance coal and limestone of these minerals, tradition asserts the existence in various parts of the island, where from the strata on the surface the modern geologist well knows it is impossible.

3854. Among the various mineral substances found in quantity in Britain, the chief are coal, lime, building and other stone, gravel, clay, fuller's earth, marl, &c. among the earths, salt, among saline substances and lead, copper and tin, among the metals. Cobalt, manganese, and some other metals and earths, are found in some places, but in small quantities. No saline or metalliferous bodies ought to be sought for, or attempted to be worked, but with the advice and assistance of an experienced and skilful mineral surveyor, nothing being more common than for proprietors to be induced by local reports or traditions to fancy their lands contain coal, lead, or some other valuable subterraneous product, and to incur great expense in making abortive trials. To ascertain the nature and value of the minerals of an estate of any magnitude, or of one of small size but of peculiar exterior organisation, it will always be worth while for the proprietor to have a mineral survey, map, and description, made out by a professional man.

3855. Coal is at present perhaps the most valuable British mineral because, among other reasons, it does not appear to be worked in any other country in such quantity as to lessen by importation the home produce. There are three species of coal, the brown, the black, and the unflammable. To the first belongs the Bovey coal or bituminous wood, found chiefly at Bovey, near Exeter to the second the slate coal, which includes the pit and sea-coal, and all the kinds in common use, and also the canal coal, which occurs only occasionally in the coal pits of Newcastle, Ayrshire, and Wigan in Lancashire to the third belong the Kilkenny coal, and Welsh culm, or stone coal, which burn to ashes without flaming.

3856. The indications of coal are different in different coal districts. In general the surface is argilla. ceous or silty, and limestone commonly forms an accompanying stratum. In some collieries near New castle, however, limestone is wanting but whinstone sandstone, and others of secondary formation, are present in a great variety of forms.

3857. The discovery of coal is made by boring and that operation is generally performed in coal districts as a guide for sinking new shafts. By this means the owners procure most essential data on which to proceed, being informed beforehand of the nature of the earth minerals, and waters, through which they have to pass and knowing, to an inch or so, how deep the coal lies, as well as the quality and thickness of the stratum found. It is confessedly of the first importance, either to the inhabitants of a district in general, or to the owners of the soil in particular to be able to detect and work such veins of coal as may exist under their soil and hence we find, on enquiry in the neighbourhood, that almost every common, moor, heath, or piece of bad land, in parts where coals are scarce, have at one time or other been reported by ignorant coal-finders to contain coal. Here many times, for instance, have our grandmothers, and nurses, repeating their stories, told us, that plenty of coals might be dug at such and such a place, if government had not prohibited their being dug, for encouraging the nursery for seamen &c. &c. Firey's enquiries, and those of Smith, have brought to light hundreds of instances, where borings and sinkings for coals have been undertaken on advice in situations in the southern and eastern parts of England attended with heavy and sometimes almost ruinous expenses to the parties, though a source of profit to the pretended coal-finders. These attempts a very slight degree of geological knowledge would have shown to be vain.

3858. The coal fields of Britain will be found scientifically described in *Outlines of Geology* by Conybeare and Phillips, and also in *Bakerwell's Geology*.

3859. Limestone, chalk and building or other stone are found in strata either on or near the surface. At a great depth it is seldom found worth while to work them. When stones of any kind are procured by uncovering the earth and then working them out, they are said to be quarried but when a pit or shaft is sunk and the materials are procured by working under ground, they are said to be mined.

3860. Gravel, chalk, clay, marl, and other loose matters, when worked from the surface, are said to be worked from a pit, and hence the terms stone, quarry gravel, clay or marl pit. Little knowledge of geology is in general required for the discovery of gravel or marl but, still, even a little would be found of the greatest advantage.

3861. The working of quarries is a simple operation, and one depending more on strength than skill. In quarrying sandstone, consisting of regular layers, the work is performed chiefly by means of the pick, the wedge, the hammer and the pinch or lever, recourse being seldom had to the more violent and irregular effects of gunpowder. But for many kinds of limestone, and for greenstone and basalt, blasting with gunpowder is always resorted to and some of the rocks called primitive, such as granite gneiss, and sienite, could scarcely be torn asunder by any other means.

3862. The heaving of lime may be considered as belonging to the subject of quarrying. This operation is performed in what are called draw kilns, or perpetual kilns. These should always be close to or near the quarry and either situated at a bank or furnished with a ramp or inclined plane of earth for carting up the coal and lime to the top of the kiln. Lime-kilns may be built either of stone or brick but the latter as being better adapted to stand extensive degrees of heat, is considered preferable. The external form of such kilns is sometimes cylindrical, but more generally square. The inside should be formed in the shape of a hexagon, or of an octagon opened a little at both ends and set on the smallest being small in circumference at the bottom, gradually wider towards the middle and then contracting again towards the top. In kilns constructed in this way it is observed, fewer coals are necessary, in consequence of the great degree of superincumbent weight which takes place in kilns formed in the shape of a square, or of a regular hexagon. Near the bottom, in large kilns, two or three apertures are made; these are small at the inside of the kiln, but are sloped wider both at the sides and the top, as they extend towards the outside of the building. The use of these apertures are for admitting the air necessary for supplying the fire, and also for permitting the labourers to approach with a drag and shovel to draw out the calcined lime. From the bottom of the kiln within, in some cases, a small building called a house is raised in the form of a wedge, and as constructed so to prevent the operation of drawing out the burned limestone, by forcing it to fall into the aperture which have been mentioned above. In other kilns of this kind, in place of this building there is an iron gate near the bottom, which comes close to the inside wall, except at the apertures where the lime is drawn out. When the kiln is to be filled, a parcel of stone or flagstone is laid at the bottom, over this a layer of coals, then a layer of limestone (which is previously broken into pieces, about the size of a man's fist) and so on alternately ending with a layer of coals, which is sown.

stone, through which, covered with coke or fuel, in order to keep the heat as intense as possible. The fire is then ignited by the furnace; and when the limestone towards the bottom is completely calcined, the fuel being constantly delivered, the limestone at the top window. The labourers then put in all additions of limestone and coal at the top, and draw out as much as they find thoroughly burned; and thus go on, till any quantity required be calcined. When limestone is burned with coke, from two barrels and a half to three and a half of calcined limestone are produced for every bushel of coal used. Limestone will, in all cases, be most economically burned by fuel which produces little or no smoke; because the necessary mixture of the fuel with the broken limestone renders it impossible to bring it in contact with a red heat, which may ignite the smoke. Dry fuel must also, in all cases, be more advantageous than moist fuel, because in the latter case a certain quantity of heat is lost in expelling the moisture in the form of vapour or smoke.

583. *Booker's lime-kiln* (Fig. 579.) is the best of all forms that have hitherto been brought into notice for burning lime with coke or other dry smokeless fuel. The kiln of this description at Closeburn is built on the side of a bank. It is circular within, thirty-two feet high from the furnace, three feet in diameter at top and bottom, and seven feet in diameter at sixteen feet from the bottom; it has cast-iron doors to the fuel-chamber (Fig. 580 a) and ash-pit (b), and a cast-iron cap or cover (Fig. 579 c, d), which turns on a pivot, and rests on a curb-ring fixed on the top of the masonry of the kiln (e). The use of this cover is to prevent the escape of more heat than is necessary to keep the fuel burning, for which yet purpose the cover has only an opening at top (f), twelve inches in diameter. The principal advantage of this construction is, that very little heat is lost, and that lime may be burned with almost as little fuel in winter as in summer. Another advantage, and one of considerable importance in a country sale, where a kiln is not worked sometimes for two or three days together, is, that by closing the orifice (f) at top, and the furnace door (Fig. 580. a b) below the fire may be kept alive for four or five days. In the ordinary descriptions of kilns without covers, the fire is usually extinguished in twenty-four hours, especially in the winter season. In Booker's kiln, one measure of coke will burn four measures of limestone. The fuel for the lime-kiln at Closeburn is brought from a distance of twenty-five miles, and it is found that one third of the expense of carriage is saved by coaling it at the coal-pit. A measure of this coke burns as much lime as the same measure of coal as when coal is used in the lime-kiln it may be said to be coked before it has much effect on the limestone. One of Booker's kilns, when coke is used, yields nearly three hundred of its contents of well burned lime every day.

580. Mouth of Closeburn coal lime-kiln. When

limestone to be burned with coal or smoky fuel, a form invented by me has been adopted at Closeburn, which from a very extensive experience, I have proved to be much superior to those in common use. This kiln, which may be designated the Closeburn coal lime-kiln (Fig. 581) is built in a similar situation to the other. It is oval in ground plan, both at top (Fig. 582), and bottom (Fig. 583), with doors to the fuel-chamber and ash-pit (Fig. 581. c, f) and an arched cover to the top (Fig. 584. g), which moves on small wheels, as shown on

and on by windlasses (h h) and has two small openings serving as chimneys for the exit of the smoke (i i). The height of the kiln is thirty-five feet; the short diameter at the fuel-chamber is twenty-two inches (Fig. 582); at the height of twenty feet the short diameter has gradually extended to five feet (Fig. 581) and this dimension is continued to the top, where the oval is nine feet by five feet (Fig. 582). As the fuel-

chamber to this kiln is very broad in proportion to its depth, these separate doors or openings become

when a greater quantity of lime is required in a certain time, than usual, as it is well known to lime-burners that the process of burning is done most economically when

586

erection of lime would take place, and another object would be gained, the drawing out of the burnt limestone for some hours, or until the limestone is so cold as not to burn the wooden structure of carts.

3865. In working a kiln with narrow circular mouths, the stone and coal should be carefully measured, so that the workman can proportion the fuel employed to the quantity of stones, and it is obvious, that the quantity of coal to be used must depend upon its relative quality and the hardness of the stone to be burnt. If this measure were adopted in kilns of any construction, the lime shells would be found better burnt.

3867. Two furnace doors are employed at the bottom of the kilns, the upper one for letting through the burnt shells [or stones] which allows at all times thorough ingress of air into the bottom of the kiln, and facilitates the drawing out of the lime, as it takes off the pressure of the stone from top to bottom of the kiln. The lower door is for drawing out the lime ashes, which is a clear gain to the lime-burner. In the long oval kiln, which consists of being made of any length, the eyes or fire-places are opposite to each other upon the two sides, which admits of a kiln being made ten or twelve feet wide at bottom, and enables the lime-burner to supply a very great demand from the kiln daily (C. G. Smart Membrs.)

necessary (fig 385) as well as advantage, for some quickly and easily drawing out the lime. In some cases, instead of a movable cover a permanent roof of masonry (fig 386) may be adopted. This roof should have proper openings to admit the supply of lime and fuel, and these may be closed by sliding shutters or hinged doors; while, in the roof, there should be a chimney for the escape of the smoke. It will readily be understood, that the use of a cover, whether fixed or movable, is chiefly to retain the heat but where the cover is a fixed structure, and sufficiently large, something will be gained by placing the fuel and limestone there, to be dried and heated before they are thrown into the kiln. Three sides of the contents of the Close-burnt oval kiln may be drawn out every day, and when it is closed at top and bottom, the fire will not go out for five or six days.

3868. Subsequent improvements by Mr. Medhurst are thus detailed in a letter to us from that gentleman, dated Feb. 25. 1850 -- I now employ kilns of an egg shape, and also oval the oval-shaped kilns are divided by arches across the kiln, descending four feet from the top the object of the arches across the kilns is to prevent the sides of the kiln falling in or contracting and also to enable you to form circular openings for feeding in the stone and coal at the mouth of the kiln. Upon this plan a kiln of any length might be constructed with numerous round mouths. In the model of the kiln lately sent to the Highland Society Bonker's conical cover may be seen revolving upon an iron ring placed upon the circular mouth and having placed a lid to the cover I am enabled to prevent the escape of heat at the top, and by cast-iron doors at the bottom the air is prevented from passing through the kiln so that by these precautions the lime burner can regulate the heat and prevent its escape for several days, when the fire would be extinguished at this season in the course of 24 hours. This is an object of great importance, as it enables you to burn lime as well, and with as small a quantity of fuel, in the winter as the summer season, and to supply the farmer with as well burned lime, at any time of the year which cannot be done in the common construction of kilns, open both at top and bottom. When coke is employed for burning lime during the day small coal should be used in the evening, in order to prevent as much as possible the escape or waste of heat during the night, from the upward circulation of air through the limestone in the kiln where coke is the fuel made use of for its calcination a kiln in which coke is the fuel employed will yield near a third more burnt lime in a given time than when coal is the fuel, so that coke may be used occasionally

when the kiln is in full action so as almost constantly to have a column of fire from the bottom to the top of the kiln, with as short intervals as possible in working the kiln. Having found that limestone is apt to be vitrified during the process of calcination, during stormy weather, from the increased circulation of air through the kiln, which adds much to the heat derived from the fuel employed, and which experienced lime-burners would have diminished, could they be aware at all times of an occurrence of this kind. From having experience of the bad effects of too great a vitrification without properly providing against it, I have reason to believe, that having a power to throw in at pleasure an additional quantity of air into the bottom of a lime-kiln, that a considerable saving of fuel necessary for the calcination of lime would be gained, that of cooling the limestone in the bottom of the kiln, which frequently retards the drawing out of the burnt limestone for some hours, or until the limestone is so cold as not to burn the wooden structure of carts.

5868. *Monkton's construction of a lime-kiln and coke oven* (Fig. 587.) has for its object to prepare quick-

lime and coke in the same kiln by a single operation, and the arrangement to effect it is at once so simple and so complete, as seemingly to provide the possibility of any material improvement. The economy of the process is likewise carried to the greatest possible degree, for that portion of the coal which is separated from it to form coke is, by its construction, rendered subservient to the burning of the limestone and the coke, owing to its increased bulk, being nearly if not quite, as valuable as coal in the market, the expense of burning is very much reduced. This kiln and oven are raised on a flat surface, the lime being raised by means of a jib and crane, though like other kilns, it might be placed on the side of a bank for supply in the usual manner. The kiln is now and has for some time past been, in full operation, at the patentee's lime-works at Maldstone. In districts where coal is dear, this will probably be found a valuable improvement, but with some descriptions of coal it is impracticable, and in all cases the labour will be considerably increased. The side walls of this kiln (a) are four feet thick, the iron bars at the bottom (b) are drawn out when the kiln is to be emptied. The limestone is raised in a box (c), by means of a jib and crane (d), when raised, the jib is swung round, and the lime-box tilted, by which the whole contents are thrown down the shaft. The coke ovens (f) may be two, or a greater or less number according to the magnitude of the works. They are supplied with coal through iron doors, which doors have a long and narrow horizontal opening in the upper part of them, to admit sufficient atmosphere air to produce combustion in the inflammable part of the coal the flames thus produced pass into the lime shaft and the flames (g) are prevented from interfering with each other by a partition wall (h). When the kiln is charged, the open lugs in front and beneath the iron bars (i) are closed, as are certain openings made in the shaft (k) and in the coke ovens (l) at convenient distances, for the purpose of introducing iron bars as rakers, to accelerate the process. When the coal is reduced to coke, it is taken out by a long-handled iron hoe, (Reg. of Arts and Soc. vol. iv p. 290.)

5870. *Burning lime in heaps* Where fuel is abundant, lime may be burned in heaps as in charring wood, or in clamps like timber. The fuel is intermixed, and the whole covered with turf or mud, so which a few holes are pierced to admit the passage of the smoke.

5871. *Machines for separating fragments* have been invented, but the effect of the powder so obtained both as a manure and for cement, is so much inferior to that of burnt lime, that they have long since been generally laid aside.

5872. *Salt* is procured from rocks, springs, and from the sea. In Chester, particularly in the neighbourhood of Northwich, the salt works are very extensive. Great quantities are got in the solid form, but not sufficiently pure for use. In this state it is conveyed from the mines to the Cheshire side of the river, nearly opposite to Liverpool. It is at this place dissolved in the sea-water, from which it is afterwards separated by evaporation and crystallization. There are also in the same district salt works, at which the salt called Cheshire salt is extracted from brine. These works are described very intelligibly by Dr Holland, in *The Report of Agriculture for the County of Cheshire*

Considerable salt-works are carried on in Scotland, and in the northern counties of England on the sea-coast, by the *evaporation of sea-water*. At Lynnhington, in Hampshire, the sea-water is evaporated to one sixth of the whole by the action of the sun and air. The works in which the sea water is heightened into brine are called *sun-works*, or *out-works*. These are constructed on a flat down or oozy beach, within a mole, which is raised, if necessary, to keep out the sea, there is a large reservoir, or feeding pond, communicating with the sea by a sluice, and adjoining to this reservoir a long trench, parallel to which there are several square ponds, called *brine pots*, in which the water is evaporated to a strong brine, and afterwards it undergoes an artificial evaporation and purification in boilers.

3873. *The metalliciferous ores or stones* should never be sought after, but in consequence of the best advice and most mature consideration. "Few," Marshal observes, "have made fortunes by mines, and many have been ruined by them." Should a man of large landed property discover a productive mine on his estate, he offers him "two words of advice. The first is, not to work it himself. A gentleman among miners is a pigeon to be plucked. Rather let the man who finds himself involved in such a predicament adopt the Cornish practice, and stipulate to take a proportional part of the ore which may be raised according to the productiveness of the mine, and the expenses of working it, jointly calculated. The other is, not to break in upon the *principal*, or gross sum, which arises from a mine. If the estate is encumbered, remove the encumbrance if not, increase its size, or, in any other prudent way, secure the *interest* of the gross produce of the mine, and thus defy the evil effects of its failure; *for no mine is inexhaustible.*"

## CHAP. VIII.

### *Establishment of Fisheries.*

3874. Fisheries may be arranged as marine, river, lake, and pond fisheries; the first being of the greatest importance to this and every country.

#### SECT. I. *Marine Fisheries.*

3875. *The importance of improving the marine fisheries* to an insular country, like Britain, is sufficiently obvious. By their augmenting the quantity of food, there would necessarily result a reduction in the prices of all the necessaries of life the condition of the labouring poor, the artificers, and tradespeople, would as necessarily be improved they would not only be the means of rearing and supporting a bold and hardy race of men for the defence of the sea-coast, but also of creating a nursery of excellent seamen for the navy in time of war, and of giving them employment when peace may render their further services unnecessary. If the fisheries flourished to that extent of which they appear to be capable, every seaport town and little village on the coasts, or on the banks of the creeks and inlets, would become a nursery of seamen. It was thus in Holland, where the national and natural advantages were very inferior to those of Great Britain for it is well observed, in the report of the Downs Society that Holland does not produce timber, iron, or salt, all of which are essential to fisheries, and all the natural produce of Great Britain; that Holland has no herrings on her own coast, while the coasts of our island abound with them and other fish, at different and at all seasons of the year, so that there are few if any, months in which shoals of this fish in particular are not found on some part of our shores and that her population is under 8,000,000, while ours amounts to about 18,000,000, giving to our fishermen six times the consumption of a home market that the Dutch have. With all the impediments to an extended use of fish in the home market, and notwithstanding the established character which the Dutch fish have always borne among foreign nations, it is consoling to find that the British fisheries are generally in a progressive state of improvement, and more particularly that most important of all their branches, the herring fishery.

3876. *The rapid progress of the herring fishery* shows that there is no art or mystery in the catching and curing of herrings that the English cannot accomplish as well as the Dutch, which is further proved by the successful experiment made by the Downs Society of fishermen in the report of whose proceedings it is stated, that herrings had been taken within the Cinque Ports of a quality so nearly resembling the deep sea fish, that they were cured and sold as the best Dutch herrings. The progressive increase of the herring fishery is confined to Scotland the quantity brought under the inspection of the officers in England amounts not to one twenty-second part of the whole, while the flourishing little town of Wick alone furnishes nearly one fifth. But the most extraordinary increase is that which has taken place in the neighbouring county of Sutherland. Till a few years past, the people of this county were contented to hire themselves as fishermen to the adventures of Wick. In 1834, they attempted, with the aid and encouragement of the Marquis of Stafford, a fishery on their own account, and the wreck of the Heilmunds was fitted up as the station. A storehouse and curinghouse were here erected, the boats were manned by the people brought from the mountains and the interior of the country. Every thing

Orkney and Shetland Islands, these fish are sent up to the London market in ice; and when the season is at its height, and the catch more than can be taken off hand fresh, they are then salted, pickled, or dried, for winter consumption at home, and for the foreign markets. Perhaps the fishery of the Tweed is the first in point of the quantity caught, which is sometimes quite astonishing, several hundreds being taken at a single draught of the net.

1856. The salmon as they are caught are packed in ice, and sent away in vessels well known under the name of Berwick smacks. Formerly it was all pickled and kitted, after being boiled, and sent to London under the name of Newcastle salmon; but the present mode has so raised the value of the fish, as nearly to have banished this article of food from the inhabitants in the environs of the fishery, except as an expensive luxury. Within memory salted salmon formed a material article of economy in all the farm-houses of the vale of Tweed, inasmuch that in-door servants often bargained that they should not be obliged to take more than two weekly meals of salmon. It could then be bought at 2s. the stone, of nineteen pounds weight, it is now never below 12s., often 36s., and sometimes two guineas.

1857. With respect to the improvement of salmon fisheries, admitting that the individual fish which are bred in any river instinctively return to the same from the sea, the most obvious means of increase in any particular river is that of suffering a sufficient number of grown salmon to go up in the spawning grounds protecting them while there, and guarding the infant shoals in their passage thence to the ocean. Even admitting that those which are bred within the British Islands, and escape the perils that await them return to these islands, it is surely a matter of some importance, viewed in a public light, to increase and protect the breed. It is a well ascertained fact, that salmon pass up toward the spawning grounds of different rivers at different seasons or times of the year consequently no one day in the year can be properly fixed by law to give them free passage up rivers in general. Perhaps every river of the island should have its particular day of liberation, which ought to be some weeks before the known close of the spawning season in a given river.

1858. In a dry season, and for want of flood water to assist them in their extraordinary efforts to gain the higher branches of a river the salmon will spawn in its lower deeper parts. But here, it is probable, few of their progeny escape the voracity of fish of prey which inhabit deep waters. While, in the shallow pebbly streams, at the heads of which they ought to lay their spawn, the infant shoal is free from danger and it is for this security, no doubt, that the instinct of the parents leads them to the greatest attainable height, at the peril of their own lives. Thus far, as to the protection of the parents, and their infant spawnings, it now remains to guard these from their native streamlets to the sea.

1859. The enemies of young salmon are fish of prey as the pike, and trout of size; both of which ought to be considered as vermin, in rivers down which salmon are wont to pass.

1860. The heron is another destructive enemy of young salmon, especially in the higher branches of rivers yet we see these common destroyers hunted up in heathen. But more wisely might the curlew be propagated and protected. The heron is tenfold more destructive of fresh-water fish, than is the curlew.

1861. The otter is a well known enemy to fish, but more so to grown salmon than to their young.

1862. The smelt is a species of vermin which is much more injurious than the otter to young salmon; during minor floods, when the young "dry" are attempting to make their escape downward in the sea, the smelt counts his victims by the score; and might boast of carrying home, in his wicker basket, a host of salmon. The net fisher is still more mischievous. But none of all the miller who takes them in his mill traps, by the bushel, or the sack, at once.

1863. The porpoise, the most audacious marine animal of prey in northern latitudes, is said to be a great devourer of salmon and other fish on the sea-coast, and in narrow seas and estuaries. It is asserted by those who have had opportunities of ascertaining the fact, that they not only destroy salmon in the narrow seas, and open estuaries, but that they have been seen guarding the mouth of a river in the salmon season, and destroying them in numbers, as they attempted to enter. If these are facts, it might be worth while for the proprietors of fisheries, or perhaps government, to offer rewards for catching this animal, and thus lessen their number, on the same principle as wolves were extirpated. The author of *The British Naturalist* affirms, from his own experience, that the seal is very easily rendered as docile and affectionate as the dog, and that it might be rendered as useful to man in fishing, as the dog is in shooting and hunting.

1864. If by wise regulations, formed into a law, the present supply of salmon could be doubled, the advantage to the community would be of some importance. When we see the great disparity of the supply between the rivers of the north and those of the south, of this island, it might not be extravagant to imagine, that the supply from the rivers of England might be made five or ten times what it is at present. One of the first steps towards regulations of this nature is to endeavour to ascertain the causes of the disparity and to profit by such as can be subjected to human foresight and control. Accurate examinations of the Tay the Tweed, the Trent, and the Thames, would, perhaps, be found adequate to this purpose.

1865. There are various modes of taking salmon, some of which may be mentioned, though it is foreign from our plan to enter into the art of fishing, which is practised by a distinct class of men, created, as it may be said, more by circumstances than regular apprenticeship or study. The situations in which salmon first attract the particular attention of fishermen, are narrow seas, estuaries, or mouths of rivers, in which they remain some time, more or less, probably, according to their states of forwardness with respect to spawning and in which various devices are practised to take them.

1866. In the wide estuary of Solway Firth, which separates Cumberland and Dumfriesshire, several ingenious methods are practised, two of which are entitled to particular notice here. Besides the open channels worn by the sea, the Solan and other rivers and brooks that empty themselves into this common estuary, the sands, which compose its base and are left dry at low water, are formed into ridges and valleys, by the tides and tempestuous weather. The lower ends of these valleys, or false channels, are wide and deep, opening downward towards the sea their upper ends grow narrower and shallower, terminating in points, at the tops of the sand-banks. As the tide flows upward, the salmon, debilitated by heat, or the current of the river to which they are destined, enter these valleys or "false beddings," on the turn of the tide, that their passage further toward is stopped, they naturally return with it into deep water, where they remain until the next tide. The natural proprietors of these sand-banks, having discovered this fact have, from time immemorial, run lines of nets, during the fishing season, across the lower ends of these lakes or valleys, half a mile, or more, perhaps, in length, the nets being

descended to such a degree, that they are lifted from the ground by the current of the tide in flowing seaward, or, if the tide does not rise sufficiently in passing beneath them into the lochs, but, on the tide's ebbing, the lower salmon fall down close to the nets, and ultimately prevent the salmon from returning. They are, in consequence, left dry, or in shallow water, and are easy to be taken, by hundreds, perhaps, at once.

3901. The other remarkable method, which is practised in the Frith of Solway is founded on a well-known habit of salmon, when they first make the land, and enter into narrow runs and coverts, to keep much along the shore: no matter whether in life, with greater certainty, their native rivers to rub off the scales with which, in general, they are more or less industed, when they return from the ocean; or to seek for food. This method of taking salmon, if not a modern invention, has recently been raised to its present degree of perfection, by an enterprising salmon fisher and farmer in the neighbourhood of Annan, who has turned it to great profit. At a short distance below the mouth of the river Annan, he has run out a long line of tall net-fences, several hundred yards in length, and somewhat obliquely from the base of the shore, with which it makes an acute angle, and closes in with it, at the upper end. Thus forming, in effect, an artificial lake: one side of which is the beach the other the net fence. The lower end is ingeniously guarded, with nets of a more trap-like construction than those which are in use for natural lochs, in which fish are found to be more quietly, until the turn of the tide. In this immense trap, great quantities, not of salmon only, but of cod, ling, sole, and other white fish are taken. Marshall knows no place in the island where sea fishing, for salmon, can be studied with so much profit as on the shores of Annandale.

3902. *Other fishing for salmon* is chiefly done with the seine, or long draught net, the construction and use of which are universally known. In rivers liable to frequent and great changes of depth and strength of current, by reason of holes and floods, it is desirable to have nets of different textures, as well as of different depths: as, one of the construction best adapted to the ordinary state of the water, and to the size of the fish that frequent it (salmon, trout, minnow, and other small-sized fish are, in some rivers, commonly taken with salmon); and another with more depth, and wider meshes, to be used during high water and strong currents, when the larger salmon do not fail to hasten upward; and the same strength of hands which is able to draw a close net on it, can work a deeper one with wider meshes. In wide rivers, with flat shores, a variety of nets are required of different lengths as well as depths, to suit every length and width of the water.

3903. *In rivers, traps are set for salmon.* The most common device of this kind is the weir or salmon leap: namely, a tall dam run across the river, with a sluice at one end of it, through which the principal part, or the whole, of the river at low water, is suffered to pass with a strong current: and in this sluice the trap is set.

3904. *The construction of salmon weirs, Marshall conceives to be, in all cases, dangerous, and in many highly injurious to the propagation of salmon: and although it would be altogether improper to denounce those which long custom has sanctioned, yet he is of opinion that it would be equally improper to suffer more to be erected; at least, until some judicious regulations are made respecting them: regulations which cannot be delayed without injury to the public.*

3905. *It now only remains to speak of poaching, or the illegal taking of grown salmon.* There are already severe penalties inflicted for this crime: which, compared with that of destroying young salmon, might, in a public light, be deemed venial, the latter deserving tenfold punishment: for the grown salmon taken in season by poachers becomes so much wholesome food; there is no waste of human sustenance by the practice. Nevertheless, as theft, the crime is great, and ought to be punishable as such. As an improvement of the present law, Marshall proposes to make the receiver, in this as in other cases of theft, equally punishable with the thief. If poachers were not encouraged by purchasers of stolen salmon, the practice would not be followed.

3906. *Lake fisheries* are of small extent, and are chiefly confined to one or two mountainous districts: and, even there, unless where char or trout abound, as in Keswick and Lochlemond, their value is small, and their improvements few. The Lochline fishery is to be considered as marine, it being in fact an inlet of the sea.

3907. *Pond-fishing* is, in most parts, peculiar to the seats of men of fortune, and the country residences of minor gentlemen. Surrey and Berkshire are, perhaps, the only districts in which fish-pools are viewed as an object of rural economy. On every side of the metropolis, something of this kind is observable. But it is on the south side, in adjoining parts of Surrey and Sussex, where the practice of fish-breeding may be said to be established. There fish-pools have been, and still are, formed with the view of letting them to dealers in carp and other pond fish, or of stocking them and disposing of the produce as an article of farm stock. In a general view of the kingdom, fish-pools can scarcely be considered as an object worthy of consideration, in the improvement of landed estates: yet there are situations in which they may be formed with profit: as in the dips and hollows of extremely bad ground: especially if waters which are genial to any of the species of pond-fish happen to pass through them, or can be profitably led to them. Even where the water which can be commanded is of an inferior quality a profitable breeding-pond may be formed to stock ponds of a more fattening nature. Feeding and fattening fish for market is commonly practised in China, and no doubt might be practised in England, with the same ease as fattening pigs. In China, boiled rice, mixed up with the blood of animals, kitchen wash, or any greasy rich fluid of animal oil, is the food with which they are fed once or twice a day: they fatten quickly and profitably.

3908. *The crayfish, though most delicious eating, and a native of England, neither abounds in sufficient quantities to be brought to market nor is reared by individuals. It requires warm rich marshy lands, and a calcareous soil.*

3909. *The limpet is an amphibious animal of the Mollusca order, common about some of the lakes in the north of England, as Keswick. Formerly considerable quantities used to be packed up and sent to London, and other places, but the market is now chiefly supplied from the Continent.*

# CHAP. IX.

## Plantations and Woodlands.

5806. *Without trees, a landed estate may be very profitable, on account of its mines, waters, and fern lands; but it will be without the noblest characteristic of territorial surface. It may possess the beauty of utility in a high degree, and especially to the owner; but it will not be much admired by the public, nor contribute greatly to the ornament of the country—for what is a landscape without wood? It is not meant, however, that plantations of trees should be made on estates for the sake of ornament; on the contrary, none need ever be made which shall not be at the same time useful, either from the products of the trees individually, or their collective influence on surrounding objects.*

5907. *Trees have been planted and cherished in all countries, and from the earliest ages; but the formation of artificial plantations chiefly with a view to profit appears to have been first practised in Britain, about the end of the sixteenth century when the insufficiency of the natural forests, which had hitherto supplied civilised society in England with timber and fuel, rendered planting a matter of necessity and profit. In the century succeeding, the improved practice of agriculture created a demand for hedges, and strips for shelter, and the fashion of removing from castles in towns and villages to isolated dwellings surrounded by verdant scenery, led to the extensive employment of trees both as objects of distinction and value. For these combined purposes, planting is now universally practised on most descriptions of territorial surface, for objects principally relating to utility and, in all parks and grounds surrounding country residences, for the joint purposes of utility and beauty. It has often been suggested, that an agreement might be made between landlord and tenant, under which it would be the tenant's interest to plant trees upon suitable parts of his farm, of little value for other purposes, and to protect them when planted. This would not only promote the interests of both, but add much to the ornament of the country. We cannot but regret that some such plan is not devised and generally adopted.*

5908. *Woodlands are lands covered with wood by nature, and exist more or less on most extensive estates. Sometimes it is found desirable partially or wholly to remove them, and employ the soil in the growth of grass or corn at other times, their character is changed by art, from coppice or fuel woods, consisting of growths cut down periodically, to trees left to attain maturity for timber.*

5909. *In our view of the subject of trees, we shall include some remarks on improving and managing woodlands, which might have been referred to the two following books but, for the sake of unity, we prefer treating of every part of the subject together. The ornamental part of planting we consider as wholly belonging to gardening, and indeed the subject of timber trees may be considered as equally one of gardening and of agriculture being the link by which they are inseparably connected. For a more extended view of the subject, therefore, we refer to our *Encyclopædia of Gardening*, and *Encyclopædia of Plants* in the former will be found all that relates to the culture of trees collectively, in the latter, all that relates to their botanical character, history, uses, height, native country and other subjects, with their individual propagation, soil, and culture. We shall here confine ourselves to the soils and situations proper for planting, the trees suitable for particular soils and situations, the operations of forming and managing artificial plantations, and the management of natural woods.*

### SECT. I. *Soils and Situations which may be most profitably employed in Timber Plantation.*

5910. *As a general principle of guidance in planting, it may be laid down, that lands fit for the purposes of aration should not be covered with wood. Where particular purposes are to be obtained, as shelter, fencing, convection, concealment, or some other object, portions of such lands may require to be wooded; but, in regard to profit, these portions will generally be less productive than if they were kept under grass or corn. The profits of planting do not depend on the absolute quantity of timber produced, but on that quantity relatively to the value of the soil for agricultural purposes. Suppose a piece of ground to let at 30s. per acre, for pasture or aration, to be planted at an expense of only 10l. per acre, then, in order to return the rent, and 5l. per cent. for the money expended, it ought to yield 30s. a year, but as the returns are not yearly, but say at the end of every fifteen years, when the whole may be cut down as a copse, then, the amount of 30s. per annum, at 5l. per cent. compound interest, being 52l. 8s., every fall of copse made at the interval of fifteen years ought to produce that sum per acre clear of all expenses. Hence, with a view to profit from the fall of timber, or copse wood, no situation capable of much agricultural improvement should be planted.*

3911. *The best situations for planting extensively are hilly, mountainous, and rocky surfaces; where both climate and surface preclude the hope of ever introducing the plough; and where the shelter afforded by a breadth of wood will improve the adjoining farm lands, and the appearance of the country.* Extensive moors and gravelly or sandy soils may often also be more profitably occupied by timber trees than by any other crop, especially near a market, collieries, mines, or any other source of local demand.

3912. *On all hilly and irregular surfaces various situations will be indicated by the lines of fences, roads, the situations of buildings, ponds, streams, &c., where a few trees, or a strip, or terrace, or row, may be put in with advantage.* We would not, however, advise the uniform mode of planting recommended by Pitt in his *Survey of Staffordshire*, and in *The Code of Agriculture*; that of always having a round clump in the point of intersection of the fences of fields. This we conceive to be one of the most certain modes ever suggested of defacing the surface of a country by planting; the natural character of the surface would be counteracted by it, and neither variety nor grandeur substituted but a monotony of appearance almost as dull and appalling as a total want of wood.

3913. *Near all buildings a few trees may in general be introduced, carefully however avoiding gardens and rick-yards, or shading low buildings.* In general fewest trees should be planted on the south-east side of cottages; and most on their north-west side; farms and farm buildings in very exposed situations (fig. 388.) and also lines of cottages, may be surrounded or planted on the exposed side by considerable masses.

3914. *Wherever shelter or shade is required, plantations are of the first consequence, whether as masses, strips, rows, groups, or scattered trees; all these modes may occasionally be resorted to with advantage even in farm lands.*

3915. *Wherever a soil cannot by any ordinary process be rendered fit for corn or grass, and only deer-trees, it may be planted, as the only, or perhaps the best, mode of turning it to profit.* There are some tracts of thin stony or gravelly surfaces covered with moss, or very coarsely with heath, and a few coarse grasses, which will pay for no improvement whatever, except sowing with the seeds of trees and bushes. These growing up will, after a series of years, form a vegetable soil on the surface. The larch, Scotch pine, birch, and a species of rough meadow willow (*Sâlix*) are the only woody plants fit for such soils. Those who have subjected to the plough old woodland, Sir Henry Stuart remarks, well know how "astonishingly even the poorest soils are ennobled by the droppings of trees, and particularly of the larch, for any considerable length of time, and the rich coat of vegetable mould which is thereby accumulated on the original surface." It would appear indeed, that on certain surfaces the growth and decay of forests are the means adopted by nature for preparing the soil for the culture of corn as on certain other soils, a stock of nutritive matter is created by peat moss, or marsh, as on the barest rocks, the rudiments of a soil are formed by the growth and decay of lichens.

3916. *Wherever trees will pay better than any other crop, they will of course be planted.* This does not occur often, but occasionally in the case of willows for baskets and hoops, which are often the most profitable crop on moist deep rich lands; and ash for hoops and crates ware, on drier, but at the same time deep and good, soils.

#### SECT. II. Trees suitable for different soils, situations, and climates.

3917. *Every species of tree will grow in any soil, provided it be rendered sufficiently dry; but every tree, to bring its timber to the highest degree of perfection, requires to be planted in a particular description of soil, situation, and climate.* The effects of soils on trees are very different, according to the kind of tree and the situation. A rich soil and low situation will secure some trees, as the larch and common pine, to grow so fast that their timber will be fit for little else than fuel; and the oak, elm, &c., planted in a very elevated situation, whatever be the nature of the soil, will never attain a timber size. In general, as to soils, it may be observed that such as promote rapid growth, render the timber produced less durable, and the contrary, that such soils as are of the same quality for a considerable depth are best adapted, other circumstances being alike, for massive-rooted trees, as the oak, chestnut, elm, ash, and most hard-wooded trees; and that such soils as are thin, are only fit for spreading or horizontal-rooted trees, as the pine and fir tribe.

5918. *A natural succession in the kind of tree has been found to take place where natural forests have been destroyed.* Evelyn noticed that, at Weston, where gradually oaks grew and were cut down by his grandfather 100 years before, beech succeeded, and that, when his brother had extirpated the beech, birch rose up. (*Gard. Mag.* vol. iii. p. 351.) In Dwight's *Travels in New England*, a number of instances are given, in some of which the pine and fir tribe were succeeded by deciduous trees, and in others the reverse. Boulange-Rodin also, and some other French and German writers, have observed the same thing to take place on the continent of Europe, and use the fact as an argument for the introduction of exotic trees to succeed the natives.

5919. *A table of soils and the trees suitable to them, which may be of some use, is given in The Agricultural Survey of Kent.* It indicates the trees which grow naturally on a variety of soils and subsoils; and, next, the sorts which yield most profit on such soils.

Surface Soil.	Subsoil.	Common Growth.	Planted Growth.	Use of
Heavy and gravelly loams.	Heavy loam with chalk.	Birch, hornbeam, oak, ash, hazel, beech, &c.	Oak, ash, chestnut, willow, Elm, wal. nut.	Timber hop-poles cordwood, hurdles, bairies for baskets, and lime-works. Ditto.
Sandy loams.	Heavy loam.	Ditto.	Elm, beech, Wey mouth pine, common spruce.	Ditto.
Flinty strong loam.	Heavy loam.	Ditto.	Willow and chestnut.	Timber fencing-poles, and as above.
Gravelly and sandy loams.	Gravelly loam.	Ash, beech, oak, hazel, &c.	Chestnut, ash.	Hop-poles, fencing-poles, and all as above.
Gravelly sandy and flinty loams.	Heavy gravelly flinty loam.	Ash, beech, hornbeam, and oak.	Ash, beech, larch, &c.	Timber, fencing, hop-poles, cordwood for charcoal, bairies, &c.
Flinty, dry poor gravelly loams.	Chalk at two feet depth with gravelly loam.	Beech, oak, &c.	Beech, larch, &c.	Cordwood, bairies, and hop-poles.
Flinty and gravelly loam.	Chalk 4 feet with deep gravelly loam.	Ash, oak, hazel, &c.	Ash, larch, &c.	Cordwood, hop-poles, bairies, stakes, &c.
Ditto.	With a few flints, but nearly as above.	Oak, hazel, beech, and ash.	Chestnut, ash, and willow.	Hop-poles, fencing-poles, stakes, cordwood, &c.
Lightish black loam.	Dry sandy gravel.	Birch, elm, ash.	Ash, elm, &c.	Various uses in husbandry.
Flinty gravelly loams.	Strong loam with flints.	Oak, ash, beech, &c.	Ash, &c.	Poles, bairies, cordwood, &c.
Chalky, flinty gravelly loam.	Chalk, with some gravelly loam.	Ditto.	Ditto.	Ditto.
Gravelly loam.	Heavy flinty and poor loam.	Oak, ash, hazel, and beech.	Ash, oak, &c.	Common produce a few poles, cordwood, bairies, &c.
Gravelly and chalky loams.	Gravelly loam with chalk.	Oak, ash, &c.	Ash and chestnut.	plantation many poles, and the above.
Gravelly loam. Ditto.	Ditto. Gravelly loam and heavy loam.	Ash, oak, & beech. Ditto.	Oak, larch. Scotch pine.	Poles, cordwood &c. Ditto. The same.
Sandy gravel.	Gravelly and sandy loam.	Ditto. Scotch pine.	Larch, chestnut, &c.	Poles, stakes, &c. &c.
Stone shatter, and gravelly loam.	Strong loam with ragstone.	Oak, hazel, birch, &c.	Birch, oak, &c.	Oaken pillars, small timber poles, &c.
Stone, chert, and gravelly loam.	Gravelly loam with some stone.	Oak, birch, aspen, hazel, and ash.	Ash, chestnut, and willow.	Fencing-poles, hop-poles, cordwood, &c.
Gravelly loam.	Gravelly loam with some stones.	Oak.	Chestnut.	Hop poles, fence poles, &c.
Sandy loam.	Gravelly loam.	Birch oak, hornbeam, &c.	Chestnut, &c.	Fence poles, hop-poles, &c.
Sandy loam and stone shatter.	Gravelly loam with ragstone.	Oak, beech, birch, hazel, ash. Ditto.	Ditto.	Ditto.
Gravelly loam and stone shatter. Ditto.	Deep loam, heavy clay and gravel. Gravelly loam.	Ditto.	Ditto.	Ditto.
Gravelly and sandy loam.	Strong clay and loam.	Oak, and ditto.	Ash larch, &c.	Poles, Elm-wood, &c. as above.
Gravelly loam. Ditto.	Gravel with clay and some flint.	Scrubby oak, hazel, &c.	Oak, ash.	Timber and ditto.
Wet spongy land.	Mud and boggy earth.	Alder willow.	Alder cedar wd. low, &c.	Hurdles, hop-poles, &c.
Drier ditto.	Ditto more dry.	Poplar.	White poplar, willow.	Hop-poles, &c.
Light sandy loam.	Dry gravelly earth.	Mountain ash, ash.	Scotch pine, silver &c.	Hop-poles.
Light gravelly loam.	White dry gravel.	Ash.	Spruce.	Timber-fencing, &c.

3920. With respect to climate, the trees which grow nearest the regions of perpetual snow are the birch, common pine, white beam, larch, mountain ash, and alder. A warmer zone is required for the sycamore and hornbeam; and still more for the beech, oak, elm, and maple. The exotic pines and firs prefer dry sheltered dingles and ravines, not far up the sides of hills, and the oak, chestnut, lime, poplars, tree willows, and a variety of American trees, will not thrive at any great elevation above the sea. The hardiest of these trees are the sycamore, beech, and alder; but on sheltered shores, or such as are little subject to the sea-breeze, pines, firs, and most sorts of trees will thrive.

3921. The sort of ground desired from planting, as whether shelter, or timber, copse, park, field, &c. and what kinds of each, must be, in most cases, more attended to than the soil, and in many cases even than the situation. The thriving of trees and plants of every kind, indeed, depends much more on the quantity of available soil, and its state in respect to water and climate, than on its constituent principles. Moderately sheltered and on a dry soil, it requires little, as far as growth is concerned, whether the surface strain be a clayey sandy, or calcareous loam: all the principal trees will thrive nearly equally well in any of these, so circumstanced: but no tree whatever in these or in any soil saturated with water and in a bleak exposed site. The durability of the timber of different trees, produced under such circumstances, will also be very different. For durability as already observed, it seems essential that every species of tree should be planted in its natural soil, situation, and climate. For hedge-row timber, those kinds which grow with lofty stems, which draw their nourishment from the subsoil, and do least injury by their shade, are to be preferred. These, according to Mistle, are oaks, narrow-leaved elm, and black Italian poplar; beech, ash, yew, and fir, he says, are ruinous to fens, and otherwise injurious to farms. (See *Hedges and Hedge-row Timber* p. 10.)

### SECT. III. Forming Plantations.

3922. The formation of plantations includes the enclosing, the preparation of the soil and the mode of planting or sowing.

3923. The enclosing of plantations is too essential a part of their formation to require enlarging on. In all those of small extent, as hedges and strips, it is the principal part of the expense; but to plant in these forms, or in any other without enclosing, would be merely a waste of labour and property. The sole object of fencing being to exclude the domestic quadrupeds, it is obvious, that whatever in the given situation is calculated to effect this at the least expense, the first cost and future repairs or management being taken into consideration, must be the best. Where stones abound on the spot, a wall is the best and cheapest of all fences as such: but, in the great majority of cases, recourse is obliged to be had to a verdant fence of some sort, and generally to one of barberry. This being itself a plantation, requires to be defended by some temporary barrier, till it arrives at maturity; and here the remark just made will again apply, that whatever temporary barrier is found cheapest in the given situation will be the best. Hedge fences are in general accompanied by an open drain, which, besides acting in its proper capacity furnishes at its formation a quantity of soil to increase the nutriment of the hedge plants,

an excavation (a), and an elevation (f), to aid in the formation of a temporary fence.

A hedge enclosing a plantation requires only to be guarded on the exterior side; and of the various ways in which this is done, the following may be reckoned among the best and most generally applicable — an open drain and paling or line of posts and rails: the plants inserted in a facing of stone, backed by the earth of the drain (b), an excellent mode, as the plants generally thrive, and almost never require cleaning from weeds, an open drain and paling and the hedge on the top of the elevation (c); no open drain, but, the soil being a loam, the surface-turves formed into a narrow ridge, to serve as a paling, a temporary hedge of furze sown on its summit, and the permanent hedge of thorn or holly within (d), and an open drain, but on the inside, the exterior being protected by a steep bank sown with furze (e). The first of these modes is the most general, the second the best, and the fourth the cheapest, where timber is not abundant. Separation fences are commonly formed in the first, second, or third manner, but with a paling on both sides. (See *Fences*, Part II. Book IV.)

3924. In the preparation of the soil for planting, draining is the first operation. Whatever may be the nature of the soil, if the plants are intended to thrive, the subsoil ought to be rendered dry. Large open drains may be used, where the ground is not to undergo much preparation; but where it is to be followed or trenched, under-drains become requisite. It is true they will in time be choked up by the roots of the trees; but by that period, as no more culture will be required, they may be opened and left open. Many situations, as steep sides of hills and rocky irregular surfaces, do not admit of preparing the soil by commencing previously to planting; but wherever that can be done, either by trenching, digging, or a year's subjection to the plough, it will be found simply to repay

the trouble. This is more especially requisite for strips for shelter, or hedge-rows, as the quick growth of the plants in these cases is a matter of the utmost consequence. The general mode of planting hedges by the side of an open drain renders preparation for them, in many cases, less necessary; but for strips of trees, wherever it is practicable, and there is at the same time no danger of the soil being washed away by rains or thaws, as in some chalky hilly districts, or blown about by the wind, as in some parts of Norfolk and other sandy tracts, preparation by a year's fallow, or by trenching two spits deep, cannot be omitted without real loss, by retarding the attainment of the object desired. Mr Withers of Norfolk not only prepares poor light land by paring, and burning, and trenching, but even spreads on it marl and farmyard dung, as for a common agricultural crop and at the same time keeps the surface perfectly free from weeds by hoeing till the young trees have completely covered the ground. The progress that they make under this treatment is so extremely rapid, as apparently to justify in an economical point of view, the extraordinary expenses that attend it. In three years, even oaks and other usually slow-growing forest trees have covered the land, making shoots of three feet in a season, and throwing out roots well qualified, by their number and length, to derive from the subsoil abundant nourishment, in proportion as the surface becomes exhausted. (*Trans. Soc. for Encour. Arts*, vol. xiv.) Cobbett (*The Woodlands*, 8vo. 1825.) recommends trenching the ground two feet deep at the least, keeping the old soil still at the top, unless there is plenty of manure, when, he says, the top soil may be laid in the bottom of the trench. There are instances stated, of promising oak plantations, from acorns dibbed into soil altogether unimproved, and of plantations of Scotch pine raised by merely scattering the seeds, without covering on a heath or common, and excluding cattle (*General Report of Scotland*, li. 368.) but these are rare cases, and the time required, and the instances of failure, are not mentioned. The practice is obviously too rude to be recommended as one of art. The best situations for planting, without any other culture but inserting the seeds or plants, are surfaces partially covered with low woody growths, as broom, furze, &c. "The ground which is covered, or rather half covered, with juniper and heath," says Buffon "is already a wood half made." Gordon, Emmerich, Hayes, Speechly Marshall, Cruikshank, and others, have shown that the most effectual method of raising oak plantations is by sowing patches of 3 or 4 acorns on dug spots, as far distant from one another as is to be the distance of the trees when half grown. The intermediate spaces, if not covered with furze, broom, or native copse, are to be planted with birch, larch, spruce, or Scotch pine. (See § 3923.)

3925 A controversy on the subject of the preparation of the soil previously to planting, has lately arisen between Sir Henry Stuart, Sir Walter Scott, Mr Withers, Mr Billington, and others, which it might be deemed improper to pass over here without notice. Scott contends, that preparing the soil accelerates the growth of the tree for a few years only, and, in as far as it has that effect, renders the timber of a less durable quality. Stuart admits the rapidity of the growth of timber on soils which have been prepared, but seems to allow with Scott, that the timber will be less durable. Withers and Billington assert, that the preparation of the soil accelerates the growth of timber without impairing its durability and the former has cited some experiments to show that oak, which has grown on good soils and rapidly has proved stronger than oak which had grown on worse soils slowly. The result of general experience, or what may be called the common sense of gardeners and foresters on this subject, seems to be this.—Preparation of the soil greatly increases the rapidity of the growth of trees, and it has not been found to lessen the strength of the timber produced on the contrary, oak, ash, willow, and poplar, when freely, or rapidly rather than slowly grown, seem to produce stronger timber, than when slowly and stuntedly grown on poor soils. But strength and durability are properties that depend on different qualities of organisation, and it is generally considered that slowly-grown timber is the most durable. We have, ourselves, no doubt of the fact, and more especially in the case of the resinous timbers. We have seen both larch and Scotch pine of a timber size, which had been rapidly grown in rich soil, and which, when cut down, had begun to decay in the heart. We would not, however, on that account cease to prepare the soil for resinous trees, as much as for the other kinds, where practicable; but we would take care to plant resinous trees only on poor soils. We have reason to believe that these opinions on the preparation of the soil for trees, and the durability and strength of timber are those of the practical men of the present day of greatest science and experience, such, for example, as Saug, Gorrie, Mann, Billington, and Cruikshank; and therefore we consider them as more especially entitled to attention in a work like the present.

3926 Whether extensive plantations should be sown or planted is a question about which planters are at variance. Miller says, transplanted oaks will never arrive at the size of those raised where they are to remain from the acorn (*Dist. Quercus*.) Marshall prefers sowing where the ground can be cultivated with the plough. (*Plant and Eng. Orn.* l. 123.) Evelyn, Emmerich and Speechly are of the same opinion; Portey and Nudd

greater planting, but offer no arguments against sowing when circumstances are such. Sang says, "It is an opinion very generally entertained, that planted timber are sown, in any case, be equal in durability and value to that which is sown. We specially feel ourselves inclined to support this opinion, although we readily admit that the matter has not been so fully established, from experiment, as to amount to positive proof. But although we have not that with decided evidence, to enable us to determine on the comparative excellence of timber raised from seeds, without being replanted, over such as has been raised from replanted trees, we are left in no doubt as to the preference, in respect of growth, of those trees which are sown, over such as are planted." (*Plant. Nat.* 48.) He particularly prefers this mode for raising extensive tracks of the Scotch pine and larch (p. 480.), and is decidedly of opinion, "that every kind of forest tree will succeed better by being reared from seeds in the place where it is to grow to maturity, than by being raised in any nursery whatever, and thence transplanted into the forest." (p. 244.) Dr. Yule (*Colled. Hort. Mem.* 4.), in a long paper on trees, strongly recommends sowing where the trees are finally to remain. "It is," says he, "a well ascertained fact, that seedlings allowed to remain in their original station, will, in a few seasons, far overtop the common named plants several years older."

2827. The opinion of Dr. Yule seems to be founded on the idea that the tap-root is of great importance to grown up trees, and that when this is cut off by transplanting, the plant has not a power of renewing it. That the tap-root is of the utmost consequence for the first three or four years, perhaps for a longer period, is obvious, from the economy of nature at that age of the plant; but that it can be of no great consequence to full-grown trees, appears highly probable from the fact, that when such trees are cut down, the tap-root is seldom to be distinguished from the others. The opinion that young plants have not the power of renewing their tap-roots, will, we believe, be found inconsistent with fact; and we may appeal to nurserymen, who raise the oak and horse-chestnut from seed. It is customary when these are sown in drills, to cut off their tap-roots without removing the plants at the end of the second year's growth, and when, at the end of the third or fourth year, they are taken up, they will be found to have produced other tap-roots, not indeed so strong as the first would have been had they remained, but sufficient to establish the fact of the power of renewal. We may also refer to the experiment recorded by Forsyth, which at once proves that trees have a power of renewing their tap-roots, and the great advantage from cutting down trees after two or three years' planting. Forsyth "transplanted a bed of oak plants, cutting the tap-roots near to some of the side-roots, or those springing from them. In the second year after, he headed one half of the plants down, and left the other half to nature. In the first season, those headed down made shoots six feet long and upwards, and completely covered the head of the old stem, leaving only a faint cicatrix, and produced new tap-roots upwards of two feet and a half long. That half of the plants that were not headed, were not one fourth the size of the others. One of the former is now eighteen feet high, and fifteen inches in circumference, at six inches from the ground: one of the latter of the latter measures only five feet and a half in height, and three inches and three quarters in circumference, at six inches from the ground." (77. *on Fruit Trees*, 4th. edit. 146.) The pine and fir trees receive much shock by transplanting; and when removed at the age of four or five years, they seldom survive of trees afterwards; those we should, on most occasions, prefer to sow especially upon mountainous tracts. But for all trees which strike, and in tolerable soils and situations, planting strong plants, and cutting them down two or three years afterwards, will, we think, all circumstances considered, be found preferable to sowing. If we make an exception, it would be for the oak in poor soils, which we would raise from the acorn in Crutshank's manner. Sir Henry Stuart (*Planter's Guide*, 3d edit. p. 482.) agrees in this opinion, with respect to deciduous trees, and considers that as the pine and fir trees receive "the greatest shock from transplanting; and as, when planted at four and five years old, they do not readily grow to timber, it is clear that they should always be sown, or at least planted, very young, in high and cold regions."

2828. On the subject of disposing the plants in plantations, there are different opinions; some advising rows, others quincunx, but the greater number planting irregularly. According to Marshall, "the preference to be given to the row, or the random culture, rests in some measure upon the nature and situation of the land to be stocked with plants. Against steep hangs, where the plough cannot be conveniently used in clearing and cultivating the interspaces, during the infancy of the wood, either method may be adopted; and if plants are to be put in, the quincunx manner will be found preferable to any. But in more level situations, we cannot allow any liberty of choice the drill or row manner is undoubtedly the most eligible." (*Plant and Nur. Ora.* p. 125.) Forsyth considers it of much less consequence than most people imagine, whether trees are planted regularly or irregularly, as in either case the whole of the soil will be occupied by the roots and the surface by the shoots. Sang and Nicol only plant in rows where culture with the horse-hoe is to be adopted. In sowing for woods and copse, the former places the patches six feet asunder and in the quincunx order. "It has been demonstrated (*Farmer's Mag.* vol. vii. p. 409) that the closest order in which it is possible to place a number of plants upon a plain surface, not nearer than a given distance from each other, is in the angles of hexagons with a plant in the centre of each hexagon." Hence it is argued, that this order of trees is the most economical; as the same quantity of ground will contain a greater quantity of trees, by 15 per cent. when planted in this form than in any other. (*Gen. Rep.* ii. 387.) It is almost needless to observe, that hedge plants should be placed at regular distances in the line, and also the trees, when these are introduced in hedges. Other plantations, and all such as like them require the soil to be dug every year, or every two years, during their subsistence, should also be planted in regular rows.

2829. The distance at which the plants are placed must depend on different circumstances, but chiefly on the situation and soil.

3928. *Planting oak, according to Miel, is the safer side to err in, because a number of plants will fall, and the successful ones can be easily removed by thinning. For bleak situations, he observes, from thirty to forty inches is a good distance, varying the distance according to circumstances. For his exposed situations, and where the soil is above six inches in depth, he recommends a distance of from five to six feet. For bays, clumps, and strips of a diameter of about one hundred feet; the margin to be planted about the distance of two feet, and the interior at three feet. In sheltered situations of a deep good soil, he recommends a distance of six feet and no more. (Fract. Plant.)*

3929. *According to Sang, "the distance at which hard-wood trees ought to be planted are from six to ten feet, according to the quality of the soil, and the exposed or sheltered situation. When the first four oaks are planted, supposing them at right angles, and at nine feet apart, the interstices will fall to be filled up with five nurseries, the whole standing at four feet and a half asunder. When sixteen oaks are planted, there will necessarily be thirty-three nurseries planted; and when thirty-six oaks are planted, eighty-five nurseries but when a hundred principal trees are planted in this manner, in a square of ten on the side, there will be two hundred and sixty-one nursery-plants required. The English acre would require five hundred and thirty-six oaks, and one thousand six hundred and ten nurseries" (Plant. Kel. 163). Pencer says, "In general cases, a distance of four feet is certainly close enough; as at that space the trees may all remain till they become saleable as rails, spars, &c.*

3930. *The number of plants which may be planted on a statute acre = 160 rods, or poles, = 4940 yards = 43560 feet, is as follows —*

Feet apart.	No. of Plants.	Feet apart.	No. of Plants.	Feet apart.	No. of Plants.
1	43,560	8	1,310	15	193
2	10,890	7	890	16	178
3	5,180	6	690	17	160
4	2,925	5	537	18	154
5	1,742	4	435	19	150
6	1,080	3	320	20	145
7	729	2	212	25	69
8	540	1	127	30	46
9	485				

3931. *The size of the plants depends jointly on the site and the kind of tree. It is universally allowed that none of the resinous tribe succeed well when removed at more than two years' growth; but if the soil is of tolerable quality prepared by digging or summer getting, and the site not bleak, plants of such hard woods as stools may be used whose stems are an inch or more in diameter.*

3932. *Miel is of opinion, "That, generally, trees three, or at most four years old from the seed, and which are from twelve to twenty-four inches high will, in any situation or soil, outgrow those of any size under eight or ten feet, within the seventh year" (Fract. Plant. 150).*

3933. *Sang observes, "the size of plants for exclusive plantations must, in some measure, depend on their kind, but it may be said, generally, that the plants being transplanted, they should be from a foot to eighteen inches in height, still in the stem and well rooted. Plants for this purpose should seldom be more than three years from the seed; indeed never, if they have been raised in good soil. Many of them may be sufficiently large at two years from the seed, and, if so, are to be preferred to those of a greater age, as they will consequently be more vigorous and healthy. The larch if properly treated, will be very fit for planting out at two years of age. A healthy seedling being removed from the seed-bed at the end of the first year, into good ground, will, by the end of the second year, be a fit plant for the forest, then one turned a second year. The next best plant for the purpose is that which has stood two years in the seed-bed, and has been transplanted for one season. This is supposing it to have risen a weekly plant, &c. if the larch rise strong from the seed the first season it should never stand a second in the seed-bed. The ash, the elm, and the sycamore, one year from the seed, nursed in good soil for a second season, will often prove sufficiently strong plants. If they be weakly they may stand two years in the seed-bed, and then, being nursed one season in good soil, will be very fit for planting out in the forest. The oak, the beech, and the chestnut, if raised in rich soil, and well furnished with roots at the end of the first year, and having been nursed in rows for two years, will be very fit to be planted out; but if they be allowed to stand two years in the seed-bed, and be planted one year in good ground, they will be still better, and the roots will be found well feathered with fine small fibres. The silver fir and common spruce should stand two years in the seed-bed. If transplanted into very good soil, they may be fit for being planted out at the end of the first year; but, more generally they require two years in the forest. The Scotch pine should also stand for two years in the seed-bed and should be nursed in good ground for one year; at the end of which they will be much fitter for being planted, than if they were allowed to stand a second year in the forest. They are very generally taken at once from the seed-bed; and, in land bare of heath or herbage, they succeed pretty well; nevertheless, we would prefer them one year nursed. The above are the hardy and most useful forest trees, and from the observations made, whatever respects the age or size of other kinds may easily be inferred." (Plant. Kel. 163).*

3934. *According to Pencer "the best general rule is, to proportion the size of the plants to the goodness of the soil, the best of the latter requiring the largest of the former. Skill, on bleak exposures, this rule will not hold good, as these the plants should never be large, for otherwise the greater part would fall from the circumstances of wind-swept and, of those that succeeded, few, if any, would make much progress for several years; pines and firs of a foot, and deciduous trees of eighteen inches, are large enough for such places. As in extensive planting, soils which are good and well sheltered but seldom occur, the most useful sizes of plants, for general purposes, will be pines and firs of a foot, and deciduous trees of eighteen inches, both transplanted. None but good-rooted plants will succeed on a bad soil, while on a good one, sheltered, none but very bad-rooted plants will fall. A large plant never has so good a root, in proportion to its size, as a small one; and hence we see the propriety of using such on good soils only. Small plants lose but few of their roots in removal; therefore, though planted in very moderate-sized holes of pulverized earth, they soon find the means of making roots, in proportion to their heads. It should never be forgotten, that, in being removed, a plant of two feet loses a greater proportion of its roots than a tree of one, and one of three feet a greater proportion than one of two, and so on, in proportion to its former strength and height; and thus, the larger the plants, so much greater is the danger of languor or weakness into which they are thrown by the operation of transplanting." (Fract. Plant. 161.)*

3935. *The seasons for planting are autumn and spring, the former when the soil and situation are moderately good, and the plants large, and the latter, for bleak situations. Necessity, however, is more frequently the guide here than choice, and in extensive designs the operation is generally performed in all moderately dry open weather from October to April inclusive. In an extensive plantation," Sang observes, "it will hardly happen but there will be a variety of soil, some parts moist and heavy, and others dry and light. The lightest parts may be planted in December or January; and the*

intermediate, or damp parts, in February or March. It must be observed, however, that if the ground be not in a proper case for planting, the operation had better be delayed. The plants will be injured, either by being committed to the ground when it is in a sour and wet, or in a dry parched, state. At a time when the soil is neither wet nor dry, the operation of planting is most successfully performed. The mould does not then adhere to the spade, nor does it run in; it divides well, and is ready to intermingle with the fibres of the plants with little trouble, and in treading and setting the plant upright, the soil is not worked into mortar, which it necessarily must be, if in a wet state, evidently to the great detriment of the plants. It is therefore improper to plant on a retentive soil in the time of rain, or even perhaps for some days afterwards, or after a fall of snow, until it has for some days disappeared. Whereas, in a dry absorbent soil, it may be proper to plant in the time of gentle showers, immediately after heavy rains, or as soon as the snow is dissolved." (*Plant. Kel. 187*)

3006. *Pocock* is a decided advocate for autumn preparation of the soil, and spring planting. "Autumn planting," he says, "is advisable only in few cases, while spring planting may properly apply to all."

3008. *According to Seng* the proper time for planting the pine and fir tribes, and all evergreens, is April, or even the first fortnight in May. "Attention should be paid, that no greater number of plants be taken from the nursery than can be conveniently planted on the same day. Damp weather is the best. When very dry and the plants rise desolate of earth at their roots, their roots should be dipped in mud (puddle) so as to be coated over by it. In all cases, care should be taken not to shake off any adhering earth from plants at the time of planting." (*Plant. Kel. 361.*)

3040. *A puddle for trees* is made by mixing water with any soil rather tenacious, so intimately as to form a complete puddle, so thick that when the plants are dipped into it, enough may remain upon the roots to cover them. The process of puddling is certainly simple, and its expense too trifling to deserve notice in its effects, however in retarding, if not attracting, moisture are such that, by means of it, late planting is rendered abundantly more safe than it otherwise would be. It is an old invention, and hence it is truly astonishing that it is not more frequently practised. If people were to adopt it generally in spring plantings, *Pocock* believes the prejudice in favour of autumn practice would soon be done away (*Tree Plant. 167*).

3041. *Cobbett* proves spring planting. "It is a great error," he says, "to suppose that you gain time by autumnal or winter planting. You do, indeed, see the buds come out a little more early in the spring but it is the effect at the end, and not at the beginning, of the summer, at which you ought to look. If you plant in the autumn or winter the plants get blown about for several months, and, in very wet weather their stems work a sort of hole round themselves; and thus the root itself is shaken. And if left thus, they will, by March, be generally leaning on one side, with the hole open on the other side; and when the harsh winds of March come upon the long-time battered ground, it will present a surface nearly as hard as a road. In such a case, the ground ought to be dug or spaded up between the trees in March or in April; for nothing can thrive well in ground thus baked, however good the ground may be in its nature." (*The Woodman, 44*.)

3042. *Pruning previously to planting.* If the plants have been brought from a distance, and the shoots roots are dried up, they should all be cut off, because, like the leaves of a tree which has been taken up in the growing state and become withered, they have lost their vitality. The larger fibres, which are only dead at the points, should be shortened. The tap-root, also, should be shortened, perhaps in most cases two thirds of its length. *Cobbett* observes, and with truth as far as our experience goes, that if the longest tap-roots "were put into the ground at full length with an iron bar, they would be sure to die all the way nearly up to the top." (*Woodman, 43*.) Many trees, however have no tap-roots, and these only require attention to the fibres. When the plants are newly taken up from the seedbed, or nursery trees, they may be planted without cutting off the fibres because these will retain their vitality unimpaired.

3043. The operation of inserting the plants in the soil is performed in various ways, the most general mode, and that recommended by Marshall and Nicol, is pitting, in which two persons are employed, one to operate on the soil with the spade, and the other to insert the plant and hold it till the earth is put round it, and then press down the soil with the foot. Where the plants are three feet high or upwards, this is the best mode but for smaller plants modes have been adopted in which one person performs the whole operation. This method of planting by pitting is what *Withers* calls the Scotch system, but which *Sir Henry Stuart* has shown (*Planter's Guide*, 2d edit. p. 468.) is not peculiar to Scotland, but is common in every country where trees are cultivated.

3044. *Seng* describes five kinds of manual operation employed by him in planting, and in part in sowing trees by pitting by sitting simply, or by cross or T sitting, by the diamond dibber by the planting-mattock; and by the planter or ground adze. In filling an area with plants, he first plants those intended as the final trees, and afterwards the nurseries; or one set of operators plant the former while another follow with the latter, unless the time for removing the nurseries, as in the case of evergreen pines and firs, should be later than that for planting the principals. "The plants, if brought from a distance, should be sloughed, i. e. earthed in; or they may be supplied daily from the nursery, as circumstances direct. All the people employed ought to be provided with thick aprons, in which to lay up the plants, the spademen, as well as the boys or girls; the latter being supplied by the former as occasion may require. All of them should regularly fill their aprons at one time, to prevent any of the plants being too long retained in any of the planters' aprons. One man cannot possibly set a plant so well with the spade, unless in the case of *laying*, as two people can; nor, supposing him to do it as well, can he plant half as many in the same space of time as two can. A boy ten years of age is equal, as a holder to the best man on the field, and can be generally had for less than half the money. Hence this method is not only the best, but the least expensive." (*Plant. Kel. 167*.)

3945. *By pitting* "The pit having been dug for several months, the surface will therefore be en-  
croached by the rains, or probably covered with weeds. The man first strikes the spade downwards to the  
bottom, two or three times, in order to loosen the soil, then pokes it as if mixing mortar for the  
builder, he next lifts out a spadeful of the earth, or if necessary two spadefuls, so as to make room for  
all the fibres, without their being anywhere crowded together. He then drops the roots turf remaining in  
the bottom and levels the whole. The boy now places the plant perfectly upright, an inch deeper than  
when it stood in the nursery and holds it firm in that position. The man strikes in the mould gently  
the boy gently moves the plant, not from side to side, but upwards and downwards, until the fibres be  
covered. The man then fills in all the remaining mould, and immediately proceeds to chop and poach  
the next pit, leaving the boy to set the plant upright, and to tread the mould about it. This in soft wet  
soil he does lightly, but in sandy or gravelly soil he continues to tread until the soil no longer retains the  
impression of his foot. The man has by this time got the pit ready for the next plant, the boy is also  
ready with it in his hand, and in this manner the operation goes on. On very steep slopes which have  
been pitted, the following rule ought to be observed in planting. — To place the plant in the angle formed  
by the activity and surface of the pit, and in finishing, to raise the outer margin of the pit highest,  
whereby the plant will be made to stand as if on level ground, and the moisture be retained in the hollow  
of the angle, evidently to its advantage. (*Plant Kai* 167.)

3946. *Mr Henry Stewart* states that the pitting system, as already practised by most nations, though by  
some ignorantly and erroneously designated the Scotch method, if duly regulated by science, must be the  
best method for the planting of waste lands, or, in general, for large designs of wood, where the quality  
of timber is the main object, although particular spots in all extensive woodlands, might be advantageously  
traced and measured under peculiar circumstances. (*Planter's Guide* 3d edit, p. 478.)

3947. *The slit method* either simply or by the T method, is not recom- mended by Sang, but necessity  
may justify its adoption occasionally. We would not recommend planting by the slit, unless where  
there is no more soil than is absolutely occupied by the fibres of the herbage which grows on the place.  
Except on turf, it cannot be performed, nor should it be practised, if the turf be found three or four  
inches thick. By pitting in summer turf is capable of being converted into a proper mould in the space  
of a few months, and the expense of pitting especially in small plantations, can never counterbalance  
the rule of success in the eyes of an ardent planter. The most proper time to perform the operation of  
sitting in the plants is when the surface is in a moist state. On all steep the plant should be placed  
towards the declivity that the moisture may fall to its roots, that is to say in planting the spademan  
should stand highest, and the boy lowest on the bank, by which arrangement the plant will be inserted  
at the lower angle of the slit. (*Plant Kai* 170.)

3948. *Planting with the diamond dibber* he says, "is the cheapest and most expeditious planting of  
any we yet know in cases where the soil is a sand or gravel, and the surface bare of herbage. The plate  
of the dibber (*fig* 590. a) is made of good steel, and is four inches and a half broad where the iron handle  
is welded to it, each of the other two sides of the triangle is five inches long, the thickness of the plate  
is one fifth part of an inch, made thinner from the middle to the sides, till the edges become sharp. The  
length of the iron handle is seven inches, and so strong as not to bend in working, which will require  
six eighths of an inch square. The iron handle is furnished with a turned bit, like the handle of a large  
gouge, both in its form and manner of being fixed on. The planter is furnished with a planting bag  
tied round his waist, in which he carries the plants. A stroke is given with the dibber a little aslant,  
the point lying inwards, the handle of the dibber is then drawn towards the person, while its plate  
remains within the ground, by this means a vacancy is formed between the back of the dibber and the  
ground, into which the planter, with his other hand, introduces the roots of the seedling plants, being  
careful to put them fully to the bottom of the opening, he then pulls out the dibber so as not to displace  
them and gives the eased turf a smart stroke with the heel and thus is the plant completely firmed.  
The greatest error the planter with this instrument can run into, is the imperfect introduction of the  
roots. Green or unpruned hands are apt to double the roots, or sometimes to lay them across the  
opening instead of putting them straight down, as above directed. A careful man however will  
become, if not a speedy at least a good planter in one day, and is of more importance that he be sure  
than quick. A careless or slowly person should never be allowed to handle a dibber of this kind.

3949. *Planting with the planting mattock* (*fig* 590. b) is resorted to in rocky or other spots where pitting  
is impracticable. "The helve or handle  
is three feet six inches long, the mouth  
is five inches broad, and is made sharp  
the length from it to the eye or hilt  
is sixteen inches and it is used to pare  
off the sward, heath or other trash that  
may happen to be in the way previously  
to easing the soil with the other end.  
The small end tapers from the eye, and  
terminates in a point, and is seventeen  
inches long. By this instrument the  
surface is skinned off "for six or eight  
inches in diameter and with the pick-  
end dug down six or eight inches deep,  
bringing up any loose stones to the sur-  
face, by which means a place will be  
prepared for the reception of the plant,  
little inferior to a pit. This instrument  
may be used in many cases, when the plants to be planted are of small size, such as one year larch seed-  
lings, one year nursed, or large year Scots pines, one year nursed and the expense is much less than by  
the spade." (*Plant Kai* 588.)

3950. *Planting with the forest planter or ground size* (*fig* 590. c) "The helve is sixteen inches long,  
the mouth is four inches and a half broad, and the length of the head is fourteen inches. The instrument  
is used in planting hilly ground, previously prepared by the hand mattock. The person who performs  
the work carries the plants in a close apron, digs out the earth sufficiently to hold the roots of the plant, and  
sets and firms it without help from another. It is only useful when small plants are used, and in hilly or  
rocky situations. (*Plant Kai* 589.)

3951. *Pontey prefers planting by pitting* in general cases, the holes being made  
during the preceding summer or winter sufficiently large, but not so deep into a retentive  
subsoil as to render them a receptacle for water. When the plants have been  
brought from a distance, he strongly recommends puddling them previously to planting,  
if they seem very much dried, it would be still better to lay them in the ground for eight  
or ten days, giving them a good soaking of water every second or third day, in order to  
restore their vegetable powers, for it well deserves notice, that a degree of moisture in  
soil sufficient to support a plant recently or immediately taken from the nursery would,  
in the case of dry ones, prove so far insufficient, that most of them would die in it. The

poddling here recommended may also be of great service in all cases of late planting where small plants are used: Fontey's method is (after poddling) to tie them in bundles of two or three hundreds each and thus send them, by a cart-load at once, to their destination, where, being set upright close to each other, and a little straw carefully applied to their outside, such bundles may remain without damage in a sheltered situation for any reasonable time necessary to plant them. Where loose soil happens to be convenient, that should be substituted in the place of straw.

3952. *Fontey's methods of planting* are in general the same as those of Sang: he uses a mattock and planter of similar shape and also a two or three pronged instrument, which we have elsewhere denominated the *planter's hack*. (*Encyc. of Gard.* § 1305.) "This instrument," he says, has been introduced of late years as an improvement on the mattock and planter, being better adapted to soils full of roots, stones, &c. it is likewise easier to work, as it penetrates to an equal depth with a stroke less violent than the former. It is also less subject to be clogged up by a wet or tenacious soil. The length of the prongs should be about eight inches, and the distances between them, when with three prongs, one and a half, and with two prongs, about two inches. The two-pronged hack should be made somewhat stronger than the other it being chiefly intended for very stony lands, or where the soil wants breaking, in order to separate it from the herbage, &c. These tools are chiefly applicable to plants of any size up to about two feet, or such as are generally used for great designs, and they are used as substitutes for the spade, in the following manner.—The planter being provided with a basket holding the plants required (the holes being supposed prepared, and the earth left in them), he takes a tree in one hand, and the tool in the other, which he strikes into the hole, and then pulls the earth towards him, so as to make a hole large enough to hold all its roots. He then puts in the plant with the other, and pushes the earth to its roots with the back of the planter after which, he fixes the plant, and levels the soil at the same instant with his foot, so that the operation is performed by one person, with a degree of neatness and expedition which no one can attain to who uses the spade. It is known to all planters, that but few labourers ever learn to plant well and expeditiously in the common method, without an assistant: this method, however requires neither help nor dexterity as any labourer of common sagacity, or boy of fifteen, or even a woman, may learn to perform it well in less than half an hour. The facility with which these tools will break clods, clear the holes of stones, or separate the soil from herbage, the roots of heath, &c. (the former being previously mellowed by the frost) may be easily imagined. (*Prof. Plant* 179.) The adoption of a small mattock for inserting plants, we recollect to have seen recommended in a tract on planting in the Highlands, by M. Laurin, a nurseryman, published at Edinburgh upwards of twenty years ago.

3953. *An expeditious mode of shi-planting* is described in the *General Report of Scotland*, as having been practised for many years on the duke of Montrose's estate. It is as follows:—"The operator with his spade makes three cuts, twelve or fifteen inches long, crossing each other in the centre, at an angle of sixty degrees, the whole

591

having the form of a star (fig 591.) He inserts his spade across one of the rays (a) a few inches from the centre and on the side next himself then bending the handle towards himself and almost to the ground, the earth opening in fissures from the centre in the direction of the cuts which had been made, he, at the same instant, inserts his plant at the point where the spade intersected the ray (a) pushing it forward to the centre, and assisting the roots in rambling through the fissures. He then lets down the earth by removing his spade, having pressed it into a compact state with his heel; the operation is finished by adding a little earth, with the grass side down, completely covering the fissures for the purpose of retaining the moisture at the root and likewise as a top-dressing, which greatly encourages the plant to push fresh roots between the swards." (Vol. II. p. 283.)

3954. *The transplantation of large trees* is a subject more properly belonging to landscape-gardening than to agriculture, but it may not be improper shortly to notice the principles of the practice in this place. As the stability of a large tree depends in a great measure on its ramose roots extending themselves on every side, as a base to the super structure, so, in preparing the tree for removal, these roots should be cut at as great a distance from the stem as can conveniently be accomplished. As the nourishment drawn up by a tree depends on the number of its fibrous roots, it is desirable, a year or two before removal, to concentrate these fibres, by limiting their production to such ramose roots as can be removed with the tree. Cut a circular trench, therefore, round the tree to be removed, at a greater or less distance, according to the size of the tree, and the exposure in which it is to be planted. Remove the earth from this trench, and also a good part of that which covers the roots which remain between the trench and the trunk. Substitute well pulverised rich soil, or mix the better part of what was taken out of the trench and off the surface with rich soil, replace it, and press the

whole firmly down. Let the tree remain two years, or three if very large, and then remove it, and carefully plant it where it is finally to remain.

355. *Sir Henry Stuart*, who has had much experience in removing large trees, and who thinks that he has discovered a new theory or principle for doing so recommends that no branches should be pruned from the head and that to prevent the tree from being blown over by the wind its position relatively to the prevailing wind of the locality should be reversed. The principle of not reducing the head in the same proportion as the roots may be reduced, was hinted at by Miller, but has been first systematically defended by Sir Henry Stuart. Experienced planters agree that nothing ought to be cut from the head of a beech tree when it is removed but they do not seem willing to con- cede to Sir Henry's theory so far as it respects most other ramous trees. We are inclined to think that he may be right with respect to ramous trees, the beech, and perhaps one or two others but that, as a general principle, whether in young trees or old, the top must be lightened more or less in proportion to the roots. When the tree has made a stock of fresh roots, and becomes firmly established in the soil, if an extraordinary exertion in its growth be then wanted, it may either be cut in or pruned severely, or cut down to the ground and in either case if it be a tree that stools, it will throw out vigorous shoots.

356. The principle of reversing the position of the tree relatively to the wind appears to be good since, the broader the base of the head of the tree relatively to its height, the more obliquely will it receive the impulse of the wind. These trees are fitted for being transplanted, which have grown in free open situations because in them the bark is thick and coarse to resist the cold the stems stout and short, and the head extensive with the lower branches spreading, to resist the wind.

357. The machine for transplanting large trees adopted by Sir Henry Stuart, is an improvement of one which has been very long in general use. It consists of a pole (Fig. 592. a) 15 feet long, attached to an axle and a pair of wheels, on which is placed a block (b), which may be of any convenient height, with a pillow (c) and two rings for attaching the draught chains (d). It is easy to conceive the application of this pole, axle, and wheels to a large tree, and its removal by men or horses to its intended destination (Fig. 593). (*Plummer's Guide*, sect. viii. 3d edit.)

SECT. IV. *Mixture of Trees in Plantations.*

3958. *The object of mixing trees in plantations is threefold: that of sheltering the weaker but ultimately more valuable kinds by the stronger and hardier that of drawing as much profit from the soil as possible and that of producing variety of appearance.*

3959. *With respect to shelter, many situations are so exposed, that it is extremely difficult to rear trees without some mode of protecting them from the cold winds of spring during their early growth. This is sometimes done by walls, the extent of whose influence, however, is but very limited by thick planting or by planting the more hardy and rapid-growing species, to nurse up and protect such as are more tender but ultimately more valuable. The proportion of nurres to principals is increased according to the bleakness of the site. Pontey says, "Both authors and planters are in the habit of erring egregiously, in regard to the proportion of principals and nurres, as they generally use as many or more of the former than the latter though it is very easy to show, that they ought to use three times as many of the latter as the former. For instance, when trees are planted at four feet apart, each occupies a surface of sixteen feet; of course, four of them will occupy sixty-four, or a square of eight feet and, therefore, if we plant three nurres to one principal tree all the former might be displaced gradually, and the latter would still stand only eight feet apart."*

3960. *Nurres plants should, in every possible case, be such as are most valued at an early period of growth. The larch and spruce fir should be used liberally in every case where they will grow freely still it is not intended they should exclude all others, more particularly the birch, which has more of the properties of a good nurre, such as numerous branches and quick growth, on any tolerable soil or situation. It is not, however like the others, a wood of general application. (Pragmatic Planter p. 113.) Sang also adopts the proportion of three nurres to one principal, and employs chiefly the resinous tribe, and looks to them for reimbursement till the hard timber has attained to a foot in diameter under which size hard timber is seldom of much value. His principals are planted at from six to ten feet apart, according to the soil and situation. (Plant. Kal. p. 163.)*

3961. *In procuring shelter, much depends on the mode of commencing and continuing plantations on bleak sites. Sang, who has had extensive experience in this part of planting, observes, that "every plain, and most fields and situations for planting in this country have what may be called a windward side which is more exposed to the destructive blast than any other. It is of great importance to be aware of this circumstance, and to be able to fix upon the most exposed side of the proposed forest plantation. Fix, then, upon the windward side of the space which is to be converted into a forest, mark off a horizontal stripe or belt, at least a hundred yards in breadth. Let this portion of ground be planted thick, say at the distance of thirty inches, or at the most three feet, with a mixture of larch, spruce, and alder in equal quantities or nearly so, if the soil be adapted for rearing these, but if it be better adapted for Scots pines, then let it be planted with them at the distances prescribed for the above mixture. We have no other kinds that will thrive better or rise more quickly in bleak situations, than these just mentioned. When the trees in this belt or zone have risen to the height of two feet, such hard-wood trees as are intended ultimately to fill the ground should be introduced, at the distance of eight or ten feet from each other, as circumstances may admit. At this period or perhaps a year or two afterwards according to the bleak or exposed situation of the grounds, let another parallel belt or zone, of nearly equal breadth be added to the one already so far grown up, and so on till the whole grounds be covered. It is not easy here to determine the exact breadth of the subsequent belt or zones this matter must be regulated by the degree of exposure of the grounds, by the shelter afforded by the zone previously planted, and by such like circumstances." (Plant. Kal. p. 99.)*

3962. *In situations exposed to the sea breeze a similar plan may be successfully followed, and aided in effect by beginning with a wall, the first zone having reached the height of the wall, plant a second, a third, and fourth, and so on till you cover the whole tract to be wooded. In this way the plantations on the east coast of Mid Lothian, round Gosford House, were reared in Sang's manner, the mountains of Blair and Dunkeld were clothed and examples, we are informed, might be drawn from the Orkney and Shetland Islands.*

3963. *The practice of mixing trees, with a view to drawing as much nourishment from the soil as possible, and giving, as it used to be said, more chances of success, was till very lately generally approved of. Marshal advises mixing the ash with the oak; because the latter draws its nourishment chiefly from the subsoil, and the former from the surface. Nicol is an advocate for indiscriminate mixture (Practical Planter p. 77), and Pontey says, "Both reason and experience will fully warrant the conclusion, that the greatest possible quantity of timber is to be obtained by planting mixtures." (Prof. Planter, p. 119.) "We are clearly of opinion," says Sang "that the best method is to plant each sort in distinct masses or groups, provided the situation and quality of the soil be properly kept in view. There has hitherto been too much random work carried on with respect to the mixture of different kinds. A longer practice, and more experience, will discover better methods in any science. That of planting is now widely extended, and improvements in all its branches are introduced. We, therefore having a better knowledge of soils, perhaps, than our forefathers had, can with greater certainty assign to each tree its proper station. We can, perhaps, at sight, decide that here the oak will grow to perfection, there the ash, and here again the beech and the same with respect to the others. If, however, there happen to be a piece of land of such a quality, that it may be said to be equally adapted for the oak, the walnut, or the Spanish chestnut, it will be proper to place such in it, in a mixed way, as the principals; because each sort will extract its own proper nourishment, and will have an enlarged range of passages for its roots, and consequently may make better timber trees."*

3964. *Opinion*, who, though by no means a scientific cultivator has in general very sound practical views is decidedly in favour of planting in masses; and would have all the trees not only of one and the same sort, but of the same size and height. (*Woodlands* § 85.)

3965. *By indiscriminately mixing* different kinds of hard wood plants in a plantation, there is hardly a doubt that the ground will be fully crapped with one kind or other; yet it very often happens, in cases when the soil is evidently well adapted to the most valuable sorts, as the oak perhaps, that there is hardly one oak in the ground for a hundred first ought to have been planted. We have known this imperfection in several instances severely felt. It not unfrequently happens, too, that even what oaks or other hard-wood trees are to be met with are overtopped by less valuable kinds, or perhaps such all things considered as hardly deserve a place. Such evils may be prevented by planting with attention to the soil and in distinct masses. In these masses are insured a full crop, by being properly nursed for a time with kinds more hardy or which afford more shelter than such hard-wood plants. There is no rule by which to fix the size or extent of any of these masses. Indeed the more various they are made in size, the better will they, when grown up, please the eye of a person of taste. They may be extended from one acre to fifty or a hundred acres, according to the circumstances of soil and situation; their shapes will accordingly be as various as their dimensions. In the same manner ought all the resinous kinds to be planted, which are intended for timber trees nor should these be intermixed with any other sort, but be in distinct masses by themselves. The massing of larch, the pine, and the fir of all sorts, is the least laborious and surest means of growing good, straight, and clean timber. It is by planting or rather by sowing them in masses, by placing them thick by a timely pruning and gradual thinning, that we can with certainty attain this object. (*Plant. Kal* 162 and 165.) Our opinion is in perfect consonance with that of Bang, and for the same reasons and we may add, as an additional one, that in the most vigorous natural forests one species of tree will generally be found occupying almost exclusively one soil and situation, while, in forests less vigorous, on inferior and watery soils, mixtures of sorts are more prevalent. This may be observed by comparing New Forest with the natural woods round Lochmoss, and it is very strikingly exemplified in the great forests of Poland and Russia.

3966. *With respect to the appearance of variety*, supposed to be produced by mixing a number of species of trees together in the same plantation, we deny that variety is produced. Wherever there is variety, there must be some marked feature in one place, to distinguish it from another but in a mixed plantation the appearance is every where the same and ten square yards at any one part of it will give nearly the same number and kinds of trees as ten square yards at any other part. "There is more variety," Repton observes, in passing from a grove of oaks to a grove of fir, than in passing through a wood composed of a hundred different species, as they are usually mixed together. By this indiscriminate mixture of every kind of tree in planting, all variety is destroyed by the excess of variety, whether it is adopted in belts, clumps, or more extensive masses. For example, if ten clumps be composed of ten different sorts of trees in each, they become so many things exactly similar but if each clump consists of the same sort of tree, they become ten different things, of which one may hereafter furnish a group of oaks, another of elms, another of chestnuts or of thorns, &c. In like manner in the modern belt, the recurrence and monotony of the same mixture of trees of all the different kinds, through a long drive, make it the more tedious, in proportion as it is long. In part of the drive at Woburn, evergreens alone prevail, which is a circumstance of grandeur, of variety of novelty, and, I may add, of winter comfort, that I never saw adopted in any other place, on so magnificent a scale. The contrast of passing from a wood of deciduous trees to a wood of evergreens must be felt by the most heedless observer and the same sort of pleasure, though in a weaker degree, would be felt, in the course of a drive, if the trees of different kinds were collected in small groups or masses by themselves, instead of being blended indiscriminately." (*Enquiry into Changes of Taste*, &c. p. 23.)

3967. *Sir William Chambers and Price* agree in recommending the imitation of natural forests in the arrangement of the species. In these Nature discriminates her plants by scattering their seeds, and the offspring rise round the parent in masses or broadly depending on a variety of circumstances, but chiefly on the facility which these seeds afford for being carried to a distance by the wind, the rain, and by birds or other animals. At last that species which had enjoyed a maximum of natural advantages is found to prevail as far as this maximum extended, stretching along in masses and irregular portions of surface, till, circumstances changing in favour of some other species, that takes the precedence in its turn. In this way it will be generally found, that the number of species, and the extent and style of the masses in which they prevail, bear a strict analogy to the changes of soil and surface and this holds good not only with respect to trees and shrubs, but to plants, grasses, and even mosses.

#### Sect. V. Culture of Plantations.

3968. *A tree, when once planted, most men consider to be done with*; though, as every one knows, the progress and products of trees, like those of other plants, may be greatly increased or modified by cultivating the soil, by pruning, and by thinning. Before proceeding to these subjects, we shall submit some remarks on the influence of culture on the progress of the growth of trees, and on the strength and durability of timber,

#### SUBSECT. I. General Influence of Culture on Trees.

3969. *The effect of culture on herbaceous vegetables is so great, as always to change their appearance, and often, in a considerable degree, to alter their nature.* The common culinary vegetables, and cultivated grasses, assume so different an appearance in our fields and gardens, from what they do in a state of wild nature, that even a botanist might easily be deceived in regard to the species. The same general laws operate upon the whole kingdom of vegetables and thence it is plain, that the effects of culture on trees, though different in degree, must be analogous in their nature. (*Treatise on Country*

*Reid, vol. II.*) In the same manner, the absence of culture, or the restraining of the vegetable to a colder climate and a worse soil, tends to contract or consolidate the parts of the plant. (*Planter's Guide*.)

3970. The effect of culture on woody plants is similar to that on culinary vegetables and cultivated grasses, but the law operates of course less rapidly, owing to the less rapid growth of trees, from the lowest bush to the oak of the forest. In all of these, the culture of the soil tends to accelerate vegetation, and, by consequence, to expand the fibre of the wood. It necessarily renders it softer, less solid, and more liable to suffer by the action of the elements.

3971. The effect of culture on the ligneous plants in common use in planting and gardening is readily exemplified. Every forester is aware how much easier it is to cut over thorns or furze trained in hedges, than such as grow naturally wild, and are exempt from culture. Gardeners experience the same thing in pruning or cutting over fruit trees, or shrubs, and the difference in the texture of the raspberry, in its wild and in its cultivated state, is as remarkable for, although the stem, in the latter case, is nearly double the thickness to which it attains in the former it is much more easily cut. On comparing the common crab, the father of our orchards, with the cultivated apple, the greater softness of the wood of the latter will be found not less striking to every arbor-culturist. The common oak in Italy and Spain, where it grows faster than in Britain, is ascertained to be of shorter duration in those countries. In the same way the oak in the highland mountains of Scotland or Wales is of a much harder and closer grain, and therefore more durable, than what is found in England though on such mountains it seldom rises to the fifth part or less of the English tree. Every carpenter in Scotland knows the extraordinary difference between the durability of Highland oak and oak usually imported from England, for the spokes of wheels. Every extensive timber dealer is aware of the superior hardness of oak raised in Cumberland and Yorkshire, over that of Monmouthshire and Herefordshire and such a dealer, in selecting trees in the same woods in any district, will always give the preference to oak of slow growth, and found on cold and clayey soils, and to ash on rocky cliffs, which he knows to be the soils and climates natural to both. If he take a cubic foot of park-oak, and another of forest-oak, and weigh the one against the other, (or if he do the like with ash and elm of the same descriptions,) the latter will uniformly turn out the heavier of the two. The Scotch pine does not stand longer than forty or fifty years on the rich and fertile land in both England and Scotland, where it is often planted, and where it rushes up with extraordinary rapidity. In the northern districts of Scotland, on the other hand, the difference between park pine and Highland pine is universally known and admitted, and the superiority of the latter is proved by its existence in buildings of great antiquity, where it is still found in a sound state a difference which can be ascribed to no other cause than the mountainous situations (that is, the natural state) in which the former timber is produced, and where, the trees being of slower growth the wood is consequently of a harder texture. A friend of Sir Henry Stewart's felled some larch trees, which had grown nearly fifty years in a deep rich loam, close to some cottages and cabbage gardens. The wood was soft and porous, and of no duration it was even found to burn as tolerable fire-wood, which larch of superior quality is never known to do. (*Tr on Coun. Res. and Planter's Guide*.)

3972. The general effect of pruning is to increase the quantity of timber produce. The particular manner in which it does this is by directing the greater part of the sap, which generally spreads itself in side-branches, into the principal stem. This must consequently enlarge that stem in a more than ordinary degree, by increasing the annual circles of the wood. Now, if the tree be in a worse soil and climate than those which are natural to it, this will be of some advantage, as the extra increase of timber will still be of a quality not inferior to what would take place in its natural state, or in other words, it will correspond with that degree of quality and quantity of timber, which the nature and species of the tree admit of being produced. If the tree be in its natural state, the annual increase of timber occasioned by pruning, must necessarily injure its quality in a degree corresponding with the increased quantity. If the tree be in a better climate and soil than that which is natural to it, and, at the same time, the annual increase of wood be promoted by pruning, it is evident that such wood must be of a very different quality from that produced in its natural state (that is, very inferior). Whatever therefore tends to increase the wood in a greater degree than what is natural to the species, when in its natural state, must injure the quality of the timber. Pruning tends to increase this in a considerable degree, and, therefore, it must be a pernicious practice, in as far as it is used in these cases. Pruning is not here considered in regard to eradicating disease, preventing injuries, or increasing the natural character and tendency of trees for those purposes it is of great advantage. Mr Knight has shown, in a very striking manner, that timber is produced, or rather, that the albumen or sapwood is rendered ligneous, by the motion of the tree, during the descent of the true (or proper) sap. It

is also sufficiently known to all who have attended to the physiology of vegetables, and is greatly confirmed by some experiments laid before the Royal Society (Phil. Trans. 1803, 1804), that the solid texture of the wood greatly depends upon the quantity of sap which must necessarily descend, and also on the slowness of its descent. Now both these requisites are materially increased by side branches, which retain a large quantity of sap, and by their junction with the stem occasion a contraction, and twisted direction of the vessels, which obstructs the progress of the (proper) juice. That this is true, in fact, is well known to those accustomed to make wine from maple and birch trees, for in this business it is found, that those trees which have fewest side branches bleed more freely than the others, but during a much shorter space of time. These hints, therefore, afford additional evidence against pruning, and particularly against pruning fir-trees, which as Mr Knight justly observes, have larger vessels than the others, and, therefore, when in an unimproved soil and climate, side branches, for the purposes above mentioned, are essentially necessary to them, if solid, resinous, and durable timber be the object in view (*Sir Henry Stuart's Planter's Guide*, p. 444.)

3978 *Sir Henry Stuart* concurring in these facts and observations, deduces the following practical conclusions respecting the influence of culture —

3976. *First* that all timber trees thrive best, and produce wood of the best quality when growing in soils and climates most natural to the species. It should, therefore, be the anxious study of the planter to ascertain and become well acquainted with these, and to raise trees, as much as possible, in such soils and climates.

3975. *Secondly* that trees may be said to be in their natural state, when they have sprung up spontaneously and propagated themselves without aid from man whether it be in aboriginal forests, ancient woodlands commons or the like. That in such trees whatever tends to increase the wood in a greater degree than accords with the species when in its natural state, must injure the quality of the timber.

3976. *Thirdly* that whatever tends to increase the growth of trees tends to expand their vegetable fibre. That when that takes place, or when the annual circles of the wood are soft, and longer than the general annual increase of the tree should warrant, then the timber must be less hard and dense, and more liable to suffer from the action of the elements.

3977. *Fourthly* that a certain slowness of growth is essentially necessary to the closeness of texture and durability of all timber but especially of the oak, and that, whenever the growth of that wood is unduly accelerated by culture of the soil (such as by trenching and manuring) or by undue superfluity of climate, it will be injured in quality in the precise ratio in which those agents have been employed.

3978. *Fifthly* that as it is extremely important for the success of trees to possess a certain degree of vigour in the outset, or to be what is technically called well set off the aid of culture is not in every case to be precluded by a consideration of the general rule. I bat if trees be in a soil and climate worse than those that are natural to them, then culture will be of some advantage as the extra increase of wood will be of a quality not inferior to what in its natural state it would obtain or, in other words, it will correspond with that degree of quality and quantity of timber which the nature of the species admits of being obtained. But culture in this case must be applied with cautious discrimination and a sound judgment. That, on the other hand, if trees be in a better soil and climate than are natural to them, and, at the same time, that the annual increase of wood be promoted by culture (as already said) it will be a decided disadvantage and deteriorate the wood. In the same way if trees be in their natural state, the annual increase of timber obtained by culture will injure its quality in a degree corresponding with the increased quantity.

3979. *Sixthly* that such appears to be a correct, though a condensed view of the operation of those general laws respecting growth, which govern the whole vegetable kingdom, and especially of their effects on woody plants, and of the salutary restraints, which science dictates to be laid on artificial culture, of a kind pruning as well as manuring forms a constituent part as has been explained above, at so much length. That it is by a diligent study of the peculiar habits of trees, and the characters of soils, illustrated and regulated by facts drawn from general experience that rash or ignorant systems of arboriculture are to be best corrected, and science brought most beneficially to bear on general practice" (*Planter's Guide*, 2d edit. p. 678.)

## SUMMARY 2. Culture of the Soil among Trees.

3980. *With respect to the culture of the soil*, it is evident, that young plantations should be kept clear of such weeds as have a tendency to smother the plants, and though this is not likely to take place on heaths and barren sites, yet even these should be looked over once or twice during summer and at least those weeds removed which are conspicuously injurious. In grounds which have been prepared previously to planting, weeding, hoeing by hand or by the horse hoe, and digging or ploughing (the two latter rarely) become necessary according to circumstances. The hoeings are performed in summer to destroy weeds, and render the soil pervious to the weather. The ploughing and diggings in winter are for the same purpose, and sometimes to prepare the soil for spring crops. These, both Ponter and Sang allow may be occasionally introduced among newly planted trees, though it must not be forgotten that, relatively to the trees, the plants composing such crops are weeds, and some of them, as the potato, weeds of the most exhausting kind. Sang uses a hoe of larger size than usual (*Ag* 590 d.) In preparing lands for sowing woods, Sang ploughs in manure, sows in rows six feet apart, by which he is enabled to crop the ground between with low growing early potatoes, turnips, and lettuce but not with young trees as a sort of nursery, as they prove more scourging crops than esculent vegetables nor with grain, as not admitting of culture, and being too exhausting for the soil. Marshall, and some other authors, however, approve of sowing the tree seeds with a crop of grain, and hoeing up the stubble and weeds when the crop is removed.

3981. *Ponter* observes, "that wherever preparing the soil for planting is thought necessary, that of cultivating it for some years afterwards will generally be thought the

man; slight crops of potatoes with short tops, or turnips, may be admitted into such plantations with advantage for two or three years, as they create a necessity for annually digging or stirring the surface, and tend very materially to accelerate the growth of the plants. It may be objected, that such crops must impoverish the soil, and no doubt such is the fact, so far as common vegetables are concerned but as to the production of wood, its support depends, in a great measure, on a different species of nutriment, and hence, I could never observe, that such cropping damaged it materially" (*Frogt. Plant.* p. 158.)

3982. *Over plantations*, for hawks, willows, and hoops, require digging and cleaning during the whole course of their existence and so do hedgerows to a certain extent, and some ornamental plantations.

#### SUMMARY 3. *Filling up of Blanks or Futures in Plantations.*

3983. *The filling up of blanks* is one of the first operations that occurs on the culture of plantations, next to the general culture of the soil, and the care of the external fences. According to Sang "a forest plantation, either in the mass form or ordinary mixture, should remain several years after planting, before filling up the vacancies, by the death of the hard-wood plants, takes place. Hard-wood plants, in the first year, and even sometimes in the second year, after planting, die down quite to the surface of the ground, and are apparently dead, while their roots, and the wood immediately above them, are quite fresh, and capable of producing very vigorous shoots, which they frequently do produce, if allowed to stand in their places. If a tree, such as that above alluded to, be taken out the first or second year after planting, and the place filled up with a fresh plant of the same kind, what happened to the former may probably happen to the latter and so the period of raising a plant on the spot may be protracted to a great length of time or it is possible this object may never be gained.

3984. *The filling up of the hard-wood lands* in a plantation which has been planted after trenching or summer fallow and which has been kept clean by the hoe, may be done with safety at an earlier period than under the foregoing circumstances, because the trees in the present case, have greater encouragement to grow vigorously after planting, and may be more easily ascertained to be entirely dead, than where the natural herbage is allowed to grow among them.

3985. *But the filling up of larches and pines* may take place the first spring after the plantation has been made because such of these trees as have died are more easily distinguished. In many cases where a larch or pine loses its top, either by dying down or the biting of hares or rabbits, the most vigorous lateral branch is elected by nature to supply the deficiency, which by degrees assumes the character of an original top. Pines, and larches, therefore, which have fresh lateral branches, are not to be displaced, although they have lost their tops. Indeed, no tree in the forest, or other plantation, ought to be removed until there be no hope of its recovery.

3986. *If the filling up of plantations be left undone till the trees have risen to fifteen or twenty feet in height* their roots are spread far abroad, and their tops occupy a considerable space. The introduction of two or three plants, from a foot to three feet in height, at a particular deficient place, can never, in the above circumstances, be attended with any advantage. Such plants may, indeed, become bushes, and may answer well enough in the character of underwood, but they will for ever remain unfit for any other purpose. It is highly improper then, to commence filling up hard-wood plantations before the third year after planting or to protract it beyond the fifth or the sixth. March is the proper season for this operation. (*Plant. Kel.* 295.)

#### SUMMARY 4. *Pruning and Heading down Trees in Plantations.*

\*3967 *Pruning is the most important operation of tree culture*, since on it, in almost every case, depends the ultimate value, and in most cases the actual bulk, of timber produced. For pruning, as for most other practical purposes, the division of trees into rustum or frondose-branched trees, and into non-rustum or branchy-headed sorts, is of use. The main object in pruning frondose-branched trees is to produce a trunk with clean bark and sound timber; that in pruning branchy-stemmed trees is principally to direct the ligneous matter of the tree into the main stem or trunk, and also to produce a clean stem and sound timber, as in the other case. The branches of frondose trees, unless in extraordinary cases, never acquire a timber size, but rot off from the bottom upwards, as the tree advances in height and age and, therefore, whether pruned or not, the quantity of timber in the form of trunk is the same. The branches of the other division of trees, however, when left to spread out on every side, often acquire a timber-like size, and as the ligneous matter they contain is in general far from being so valuable as when produced in the form of a straight stem, the loss by not pruning off their side branches or preventing them from acquiring a timber-like size is evident. On the other hand, when they are broken off by accident, or rot off by being crowded together, the

tumber of the trunk, though in these cases increased in quantity, is rendered knotty and rotten in quality.

3988. *Pruning frondose or resinous trees* is one of the greatest errors in the modern system of forest management. The branches of the different species of pines, and of the cedar of Lebanon, never attain a timber size, if growing in a moderately thick plantation those of the fir tribe never under any circumstances. Provided pines and cedars, therefore, are planted moderately thick, so loss in point of timber can ever be sustained by omitting altogether to prune them and in this respect the fir tribe, whether thick or thin on the ground, may be left to themselves. The important question is, how does the rotting off of the branches affect the tumber in the trunk of the tree? Certainly no pine or fir tumber can be sounder or better than that which is brought from the native forests of the north of Europe, and from America, where no pruning is ever given. The rotting off of the frondose branches, therefore, cannot be injurious in these countries. The next question is, can it be proved to be injurious in this country? We are not aware that it has, and do not believe that it can. The rotting off of the branch of a resinous tree is a very different process from the rotting off of a branch of a ramose-headed tree. This fact may be verified by observing what takes place in pine or fir woods, and by inspecting the interior of foreign pine or fir cut up into planks. In the rotting off of side branches of deciduous trees, we find, that the principal part where decay operates, at least in all the soft woods, and even in the oak when it is young, is the heart but in the rotting off of the side branches of resinous trees, we shall find them decaying chiefly on the outside, and wearing down the stump of the fallen branch in the form of a cone. On examining the sections of sound foreign deal, we shall find that the knots of the side branches always terminate in cones when the section is made vertically. This is a fact well known to every carpenter and it is also known to a great many, that British pine and fir timber that has been pruned, has invariably a rotten space at every knot. The same thing is observable to a certain extent in the natural decay of the side branches of all trees. When the decay is natural, it commences at the circumference, and wears down the stump, till it ends in a small hard cone, which is buried in the increasing circumference of the tree, and is never found injurious to the tumber when the decay is artificial, or in consequence of excessive pruning that is, suddenly exposing a large section to the action of the atmosphere, the bark protects the circumference, and the decay goes on in the centre, so as to end in forming an inverted cone of rotten matter which serves as a funnel to conduct moisture to the trunk, and thereby render it rotten also. The conclusion which we draw from these facts is, that the pine and fir tribe should scarcely be pruned at all, and that no branches of ramose trees should be cut off close to the stem of a larger size than what may be healed over in one or at most two seasons. We agree with Cruickshank therefore, when he says, "It would appear that the pruning of firs [the pine and fir tribe], supposing it harmless, can yet be productive of no positive good."

3989. Cruickshank, Pottley and Song agree that the great object of pruning is to protect the leader or main stem or shoot from the rivalry of the side branches, in order that as much of the nourishment drawn from the soil may be employed in the formation of straight tumber and as little in the formation of branches and spray as is consistent with the economy of vegetation. Without the agency of the leaves the moisture absorbed from the soil could no more nourish a plant than the food taken into the stomach would nourish an animal without the process of digestion. The branches bearing the leaves are therefore just so necessary to the welfare of the tree as the roots. By taking away too many of the branches, only a small part of the fluid imbibed will be elaborated; by leaving the branches too thick and crowded, the leaves may be less perfect, and less fit for performing their office, than they otherwise would be. Exposure of a part of the branches to the light and air may therefore be a sufficient reason for thinning them independently of increasing the trunk. "How asks Cruickshank, "are we to know the exact number of branches that may be removed with safety in any given circumstances? Never it is answered, displace any which have not already got, or seem in immediate danger of getting the upper hand of the leader. These will be known by their equalling or approaching the leader in size, or to speak less ambiguously by their being of the same, or nearly of the same, girth at the place where they spring from the stem, as the stem itself is at their length from its top." In proceeding according to this plan, the pruner is not to regard in the smallest degree, the part of the stem on which a shoot is situated. If it is too large, it must be displaced, should it be in the highest part of the tree if it is not too large, it must remain though it be close to the ground.

"But how will this method, the reader may be ready to ask, ever produce a clean stem? By repeating the pruning, it is answered, as often as the growth of the branches may make the operation necessary. Suppose, the first time a tree undergoes the process, that the branches removed are a considerable distance from the ground, and that there are several smaller ones left growing further down the stem; these last will gradually increase in size till they too, must be lopped off and thus the stem will be in the end as effectually cleared, though more gradually and consistently with the health of the tree, as by the abrupt method represented above.

"If any branches that were left at a former pruning lay on the stem, appear at the next repetition of the process not to have increased in size, we may safely conclude that they have had no influence on the tree either good or bad and as it would be in vain to leave them with the hope that they will any longer assist in the elaboration of the sap, they should be removed, as unsightly objects which it is no longer useful to preserve." (*Practical Planter* p. 108.)

3990. *Milford* considers the leaves and branches of trees as of the greatest importance he thinks every timber tree ought to have the trunk clothed with branches throughout; but these branches he would shorten in such a way that they should never engross any material part of the tumber of the tree. To accomplish this, it is necessary to commence pruning when the trees are young, by which means the great bulk of the timber produced will be deposited in the main stem or trunk. This is what he calls *preventive pruning* (*Gard Mag* vol. vi.) A similar system had been recommended by Mr. Blake of

Hollahan, under the name of *forestorizing* and is advocated by Sir Henry Stuart, under that of *artificial pruning*.

3991. *Most erroneous opinions on the subject of pruning ravenous trees* have been propagated by Salmon, the experienced manager of the late Duke of Bedford, Ponty forest-pruner to the same duke, and others of less note. Sang on the other hand, argues against excessive pruning of the ravenous tribe of trees as injurious to the health of the tree and the soundness of its timber. Ellen, also, a gardener of scientific acquirements, and extensive experience in England, his native country, and in Scotland and Ireland, would never prune the pine and fir tribe at all, unless when very young, and when the side shoots could be pinched off with the finger and the thumb. At a more advanced age, if compelled by circumstances to prune, he would only shorten the extremities of the fronds. Of two trees, pines, firs, cedars, or larches, the one pruned and the other unpruned, there will be found, he says, most timber in the trunk of the unpruned one while the branches are so much in addition to the value of the tree. He excepts, of course, those cases in which frondose branches take a ramose character in consequence of the tree standing alone, as is frequently the case with the cedar of Lebanon, and sometimes with the Scotch pine.

3992. *Our own opinion* with respect to pruning the ravenous trees is in accord with that of Ellen and Cruickshank and as to hard and soft wooded leaf trees, we think Cruickshank's practice and rule unexceptionable. We would prune the last description of trees much less than is generally done, and leave the pine and fir tribe in a great measure to nature taking care, however to thin betimes and occasionally from infancy till the maturity of the trees. We have no doubt of this, that when the larch and Scotch pine trees planted in the end of the last century, and severely pruned for the first twenty or twenty five years of the present, shall come to be cut down and sawn up, their timber will be found full of faults, and of very little value compared with timber of the same sorts from natural and unpruned woods, foreign and domestic.

3993. *With respect to the manner of pruning* Sang observes, "Where straight timber is the object, both classes in their infancy should be feathered from the bottom upwards,

keeping the tops light and spiral, something resembling a young larch (fig. 594 a). The proportion of their tops should be gradually diminished, year by year, till about their twentieth year when they should occupy about a third part of the height of the plant that is, if the tree be thirty feet high the top should be ten feet (b). In all cases in pruning off the branches, the utmost care must be taken not to leave any stumps sticking out, but cut them into the quick. It is only by this means that clean timber can be procured for the joiner or slightly stemmed trees to please the eye. It is a very general practice to leave snags or stumps (c) before the bole can be enlarged sufficiently to cover these, many years must elapse the stumps in the mean time become rotten and the consequence is, timber which, when sawn up (d), is only fit for fuel."

3994. *The general seasons of pruning* are winter and spring, and for the gean or wild cherry midsummer as it is found to gum very much at any other season. Pontey says, "As to the proper seasons of pruning, there is only one difficulty and that is, discovering the wrong one, or the particular time that trees will bleed. Only two trees have been found which bleed uniformly at certain seasons, namely the sycamore and fir, which bleed as soon as the sap begins to move." There is, however, one season for pruning unquestionably preferable to all others, as far as the welfare of the tree and the soundness of its future timber is concerned. It is well known to physiologists and observing gardeners, that when the sap is returning, wounds heal with the greatest rapidity. Hence in all plants which are difficult to strike from cuttings, the gardener makes choice of the point of a shoot in that particular stage of maturation when the sap is returning that is, when the base of the shoot is beginning to assume a ligneous character. This in hardy trees, is uniformly a week or a fortnight after midsummer, and it will be found that the wounds made by cutting off branches at that season, or any time within three weeks after midsummer will, in the course of four or five weeks, be partly covered with a callosity proceeding from the lips of the wound. Wounds made by cutting branches off the same trees, five weeks after midsummer, will remain without the slightest indi-

cation of healing at the edges till the following spring, and if the tree is delicate, or the winter severe, they will then be in a worse condition than if they had not been pruned at all the lips of the wounds will have begun to decay. The only seeming contradiction to this general law in trees is where what are called second growths are produced, as in the oak and some other trees, and in such cases there is of course a second returning sap, for the same reason that there was at first. (*Gard. Mag.* vol. vi p. 84)

3995 *In spring pruning* does not when bleeding takes place. As a general rule, Pontey thinks "summer preferable to winter pruning" because, in proportion as wounds are made early they heal so much more in the same season. (*Forest Primer* 236.) Sang suspends pruning from the end of February to the middle of July but carries it on during every other month of the year pruning the wild cherry or any other tree very apt to gum, only in July and August. (*Plant Kal.* 935.)

3996 *With respect to the implements to be used*, Sang observes, "In every case where the knife is capable of lopping off the branch in question, namely, in the pruning of infant plants it is the only instrument necessary. All other branches should be taken off by the saw. A hatchet, or a chisel, should never be used. Every wound on the stem or bole should be quite into the quick, that is, to the level and depth of the bark, nor should the least protuberance be left. The branch to be lopped off by the saw should, in all cases, be notched or slightly cut on the under side, in order to prevent the bark from being torn in the fall and when the branch has been removed, the edges of the wound, if anywise ragged, should be pared smooth with the knife. If the tree be vigorous, nature will soon cover the wound with the bark, without the addition of any plaster to exclude the air. In the shortening of a strong branch, the position of which is pretty upright it should be observed to draw the saw obliquely across it, in such a manner as that the face of the wound shall be incapable of retaining moisture and afterwards to smooth the edges of the bark with a knife" (*Plant Kal.* 181.) In every case where the branches are too large for the knife, Pontey prefers the saw, as the best and most expeditious instrument and one the use of which is more easily acquired by a labourer than that of either the bill or axe. In 'large work' he uses the common carpenter's saw for smaller branches, one with somewhat finer teeth, with the plate of steel, about twenty inches long.

3997 *The pruning of all deciduous trees should be begun at the top, or at least those branches which are to be removed thence should never be lost sight of.* "Having fixed upon what may be deemed the best shoot for a leader or that by which the stem is most evidently to be elongated and enlarged, every other branch on the plant should be rendered subservient to it, either by removing them instantly or by shortening them. Where a plant has branched into two or more rival stems, and there are no other very strong branches upon it nothing more is required than simply to lop off the weakest clean by the bole leaving only the strongest and most promising shoot. If three or four shoots or branches be contending for the ascendancy they should in like manner be lopped off, leaving only the most promising. If any of the branches which have been left farther down on the bole of the plant at former prunings have become very strong or have extended their extremities far they should either be taken clean off by the bole, or be shortened at a proper distance from it, observing always to shorten at a lateral twig of considerable length. It is of importance that the tree be equally poised and therefore, if it have stronger branches on the one side than on the other, they should either be removed or be shortened. Thus, a properly trained tree, under twenty feet in height, should appear light and equal, from within a yard or two of the ground to the upper extremity its stem being furnished with a moderate number of twigs and small branches, in order to detain the sap and circulate it more equally through the plant.

3998 *The subsequent pruning of trees of this size standing in a close plantation will require much less attention* all that is wanted will consist in keeping their leading shoots single. From the want of air their lateral branches will not be allowed to extend, but will remain as twigs upon the stem. These, however frequently become dead branches and if such were allowed to remain all on the tree, they would indubitably produce blight and calculated greatly to diminish the value of the timber. Hence the impropriety of allowing any branch to die on the bole of a tree indeed, all branches should be removed when they are alive such a method, to our knowledge, being the only sure one to make good timber. From these circumstances, an annual pruning or at least an annual examination, of all forests is necessary. (*Plant Kal.*)

3999 *Heading down* such non-venous trees as stals, we have already stated to be an important operation. After the trees have been three or four years planted, Sang directs that "such as have not begun to grow freely should be headed down to within three or four inches of the ground. The cut must be made with the pruning-knife in a sloping direction, with one effort. Great care should be taken not to bend over the tree in the act of cutting. By so bending the root may be split, a thing which too often happens. The operation should be performed in March and not at an earlier period of the season, because the wounded part might receive much injury from the severe weather in January and February, and the expected shoot be thereby prevented from rising so strong and vigorous." (*Plant Kal.* 357.) Huron, in a *Memoir on the Culture of Woods* presented to the French government in 1746, says he has repeated this experiment so often, that he considers it as the most useful practice he knows in the culture of woods.

4000 *For the purpose of producing heads for ship timber* various modes of pruning have been proposed, as such heads always fetch the highest price. According to Pontey "it is hazardous by saying, that if plenty of long, clean, straight, free grown trees could be got, steaming and a screw apparatus would form heads."

4001 *Monteth*, a timber valuator of great experience and in extensive practice says, the value of the oak, the broad-leaved elm, and Spanish chestnut, depends a good deal on their being crooked, as they are all used in ship building. He says he has seen trees successfully trained into crooked shapes of great value, in the following manner:—"If you have an oak, elm, or chestnut, that has two stems, as it were, striving for the superiority, lop or prune off the straight stem and if a tree that is not likely to be of such value be standing on that side to which the stem left seems to incline to a horizontal position, take away the tree, and thus give the other every chance of growing horizontally. At this time it will be necessary to take away a few of the perpendicular shoots off the horizontal branch and, indeed, if these branches, which is sometimes the case in such trees, seem to contend, take away most of them. But if they do not, it is better at this time not to prune over much, except the crooked shoots on the horizontal branch, till they arrive at the height of fifteen or even twenty feet. By this time it will be easily seen

what kind of tree it is likely to form; and, if it inclines to grow crooked, lighten a little the top of the tree, by taking off a few of the crooked branches on the straighter side, allowing all the branches to remain on the side to which the tree inclines to crook, to give it more weight, and to draw most of the juice or sap that way and it will naturally incline more to the crook. at the same time clearing away any other tree on the crooked side, that may be apt, with the wind, to whip the side of the tree to which it inclines to crook. Also taking away such trees of less value as may prevent it from spreading out to the one side more than to the other." He adds, "I have myself tried the experiment with several oak trees at about twelve feet high, that were a little inclined to crook, and that had also a main branch inclined to a horizontal position. In the course of less than twenty years, I had the pleasure of seeing some of these very trees grow so very crooked that the branch would work in with the main stem or body of the tree to a complete knee or square, which is the most valuable of all trees, and, as ten trees of crooked oak are required for one straight one, it is of the most essential consequence to have crooked oak trees; and, besides, an oak tree, properly crooked, that will answer for a large knee (say the main branch, to be fit to work in with the body or trunk of the tree without much waste of wood) is nearly double in value to the same number of feet of a straight tree and, indeed, knees of oak are extremely scarce, and difficult to be got."

4002. *Powley* "knows of no way by which knots of tolerable scantlings (knees excepted) can be produced with certainty and little trouble, but from a side branch kept in a bent position by the branches of another tree or trees overhanging its stem" (*Forest Primer* 174.)

4003. *Coppice woods*, in so far as grown from poles or bark, require pruning on the same principle as timber trees, in order to modify the ligneous matter into stem, and produce clean bark. In as far as they are grown for fence wood, fuel or besom spray, no pruning is required.

4004. *Oser holls* require the laterals to be pinched off the shoots intended for hoops those of the basket-maker seldom produce any. The stools, also require to be kept free from dead wood, and stunted knotted protuberances.

4005. *Hedges* require side pruning or switching from their first planting, so as gradually to mould them into "the wedge shape, tapering from bottom to top on both sides equally till they meet in a point at the top. Two feet at bottom is a sufficient breadth for a five feet hedge. a greater or less height should have the bottom wider or narrower accordingly. In dressing young hedges, either of the deciduous or evergreen kinds, the sides only should be cut till the hedge arrives at the proposed height, unless it be necessary for the sake of shelter to cut their tops over, in order to make the hedges thicker of branches. Such cutting of the upright shoots, however is not of any great use in this respect because every hawthorn hedge sends out a number of side shoots, which, if encouraged, by keeping the top wedge-shaped as above, will make it abundantly thick." (*Seng* 447.) In pruning hedges, some use shears but the hedge-bill is the most proper instrument, producing a smooth unfractured section, not so apt to throw out a number of small useless shoots which generally follow the crushing cut of the shears.

4006. *Hedge-row trees* require to be pruned to a tall, clean, erect stem, as at once producing more timber, and doing least injury to the ground under their drip and shade.

4007. *Trees in strips for shelter or screens for concealment*, ought to be furnished with branches, from the bottom upwards unless undergrowth supply this deficiency. Where this is not the case, care should be had that the trees be pruned into conical shapes, so as that the lower branches may be as little as possible excluded from the influence of the weather by the upper ones.

4008. *Trees for shade*, where shelter from winds is not wanting, should be pruned to ample spreading heads with naked stems. the stem should be of such a height that the sun's rays, at midday in midsummer, may not fall within some yards of the base of the trunk, thus leaving under the trees, as well as on their shady side, a space for the repose of men or cattle.

#### SUBJECT 5. *Thinning young Plantations.*

4009. *The properly thinning out of plantations*, *Seng* observes, "is a matter of the first importance in their culture. However much attention be paid to the article of pruning, if the plantation be left too thick, it will be inevitably ruined. A circulation of air, neither too great nor too small, is essential to the welfare of the whole. This should not be wanting at any period of the growth of the plantation, but in cases where it has been prevented by neglect, it should not be admitted all at once, or suddenly. Opening a plantation too much at once, is a sure way to destroy its health and vigour. In thinning, the consideration which should, in all cases predominate, is to cut for the good of the timber left, disregarding the value of the thinnings. For if we have it in our choice to leave a good, and take away a bad plant or kind, and if it be necessary that one of the two should fall, the only question should be, by leaving which of them shall we do most justice to the laudable intention of raising excellent and full-sized timber for the benefit of ourselves and of posterity? The worst tree should never be left, but with the view of filling up an accidental vacancy."

4010. *Schwen*, from observations on the most orderly and thriving plantations at Woburn, deduces the following rule for thinning:—"Keep the distance of the trees from each other equal to one-fifth of their height. In the application of this rule for thinning, it is evident that each individual tree can never be made to supply; for the original distance (even if planted in the most regular order) will allow only of

certain modifications, by taking out every other tree, and so on, but even if the obtaining of such equal distances were practicable, experience would show that another way should be preferred, of which this eye must be the judge, by taking out such trees as are least thriving, stand nearest another good tree &c. &c. at the same time keeping in view the rule prescribed. By measuring a chain square, or any quantity of land, and counting the trees thereon, then trying the height of two or three trees in that quarter and taking one fifth of such for the distance. It would be readily seen how many trees should be contained in the piece measured, or the practice may more simply be regulated by taking the distance of eight or ten trees added together, the average of which should be equal to a fifth of the height of the trees. (*Smith's Mechanisms* vol. ii. p. 305.)

4011. *In thinning mixed plantations*, the removing of the nurseries is the first object which generally claims attention. This, however, should be cautiously performed, other wise the intention of nursing might, after all, be thwarted. If the situation be much exposed it will be prudent to retain more nurseries, although the plantation itself be rather crowded, than where the situation is sheltered. In no cases, however, should the nurseries be suffered to overtop or whip the plants intended for a timber crop, and for this reason, in bleak situations and when perhaps particular nursery plants can hardly be spared, it may be sometimes necessary to prune off the branches from one side entirely. At subsequent thinnings, such pruned or disfigured plants are first to be removed, and then those which from their situation, may best be dispensed with.

4012. *At what period of the age of the plantation the nurseries are to be removed*, cannot easily be determined, and, indeed, if the nurseries chiefly consist of larches, it may with propriety be said, that they should never be totally removed, while any of the other kinds remain. For, besides that this plant is admirably calculated to compose part of a beautiful mixture, it is excelled by few kinds, perhaps by none as a timber tree. But when the nurseries consist of inferior kinds, such as the mountain ash or Scots pine, they should generally be all moved by the time the plantation arrives at the height of fifteen or twenty feet, in order that the timber trees may not, by their means, be drawn up too weak and slender.

4013. *How long this time it may probably be necessary to thin out a part of the other kinds*. The best, shalable and the least thriving plants, should first be condemned, provided their removal occasion no blank or obstar, but where this would happen they should be allowed to stand till the next or other subsequent revision.

4014. *At what distance of time this revision should take place* cannot easily be determined, as the matter must very much depend on the circumstances of soil, shelter, and the state of health the plants may be in. In general the third season after will be soon enough, and if the plantation be from thirty to forty years old and in a thriving state, it will require to be revised again, in most cases within seven years. But one invariable rule ought to prevail in all cases, and in all situations, to allow no plant to overtop or whip another. Respect should be had to the distance of the tops, not to the distance of the roots, of the trees. For some kinds require more head room than others, and all trees do not rise perpendicular to their roots, even on the most level or sheltered ground.

4015. *With respect to the final distance to which trees standing in a mixed plantation should be thinned*, it is hardly possible to prescribe fixed rules, circumstances of health, soil, the spreading nature of the tree and the like, must determine. Whether the trees are to be suffered to stand till full grown, which of the kinds the soil seems best fitted for, whether the ground be flat or elevated, and whether the situation is exposed or sheltered, are all circumstances which must influence the determination of the ultimate distance at which the trees are to stand. It may however be said, in general, that if trees be allowed a certain distance, of from twenty five to thirty feet, according to the kinds and manner of growth, they will have room to become large timber.

4016. *Twenty* shows, that forty feet distances are necessary (or only about twenty seven to the acre) to the unassisted growth of large oak trees owing to the flat spreading, and close form of their heads, but that the properly trained open, high, and conical heads of such trees will admit of their standing at twenty five feet distances, or about seventy trees on the acre, and of the most profitable kind. What an inducement to pruning and management! (*Ferry's Derbyshire*, vol. i. p. 58.)

4017. *Plantations of Scots pine*, if the plants have been put in at three, or three and a half feet apart, will require little care until the trees be ten or twelve feet high. It is necessary to keep such plantations thick in the early part of their growth, in order that the trees may tower the faster, and push fewer and weaker side branches. Indeed, a pine and a soft wood plantation should be kept thicker at any period of its growth than plantations consisting of hard wood and nurseries already mentioned, and it may sometimes be proper to prune up certain nursery plants, as hinted at above (4011) for nurseries in a mixed plantation. Those pruned-up trees are of course to be reckoned temporary plants, and are afterwards to be the first thinned out. Next to these, all plants which have lost their leaders by accident, should be condemned, because such will never regain them so far as afterwards to become stately timber, provided that the removal of these mutilated trees cause no material blank in the plantation. Care should be taken to prevent whipping, nor should the plantation be thinned too much at one time, lest havoc be made by prevailing winds, an evil which many, through inadvertency have thus incurred. This precaution seems the more necessary, inasmuch as Scots pines, intended for useful large timber, are presumed never to be planted except in exposed situations and thin soils. At forty years of age, a good medium distance for the trees may be about fifteen feet every way. It may be worthy of remark, that after a certain period, perhaps by the time that the plantation arrives at the age of fifty or sixty years, it will be proper to thin more freely in order to harden the timber, and that then this may be done with less risk of danger from the strength the trees will have acquired, than at an earlier period, but still it should be done gradually.

4018. *Plantations of spruce and silver fir*, intended for large useful timber, should be kept much in the manner above stated, both in their infancy and middle age. As already remarked, planting and keeping them as thick as is consistent with their health are the best means of producing tall straight, clean stems, and valuable timber. When planted for screens or for ornament, they require a different treatment. "To larch

plantations, the above observations will also apply, and indeed they are applicable to plantations of all kinds of resinous trees.

4019. *The exposed margin of all young plantations should be kept thicker than the interior.* The extent to which this rule should be carried must be regulated according to the degree of exposure of the situation, the age of the plants, the tenderness of the kinds, and other circumstances.\*

4020. *The proper season for thinning is autumn, or very early in the spring where the trees are to be taken up by the root and replanted elsewhere winter for thinning for timber and fuel; but such trees as are valuable for their barks should be left untouched till the sap rises in April or May.*

4021. *Copse-woods require thinning when young, like other plantations, and when once established the stools require to be gone over the second year after cutting and all superfluous suckers and shoots removed.* This operation should be repeated annually, or every two or three years, in connection with pruning, till within three or four years of the general fall of the crop.

#### SECT VI Improvement of Neglected Plantations.

4022. *Neglected and mismanaged plantations* will include the greater number in Britain. The artificial strips and masses have generally never been thinned or pruned and the natural woods, or copse-woods, have for the most part been improperly thinned or cut over. It is often a difficult matter to know what to make of such cases, and always a work of considerable time. "Trees," Sang observes, "however hardy their natures may be, which have been reared in a thick plantation, and consequently have been very much sheltered, have their natures so far changed, that, if they be suddenly exposed to a circulation of air, which, under different circumstances, would have been salutious and useful to them, they will become sickly and die. Hence the necessity of admitting the air to circulate freely among trees in a thick plantation, only gradually, and with great caution." This precaution is particularly necessary in thinning plantations of Scotch pine. Trees which have been screened by each other for forty or fifty years, cannot bear the loss of their near neighbours.

4023. *A plantation which has become close and crowded,* having been neglected from the time of planting till perhaps its twentieth year should only have some of the smallest and most unightly plants removed one perhaps in every six or eight, in the first season in the following season, a like number may be removed and in two or three years afterwards, it should be gone over again, and so on till it be sufficiently thinned. It will be proper to commence the thinning at the interior of the plantations, leaving the skirts thicker till the last indeed, the thinning of the skirts of such a plantation should be protracted to a great length of time. With thinning, pruning to a certain extent should also be carried on. "If the plantation," Sang observes, "consists of pines and firs, all the rotten stumps, decayed branches, and the like, must be cut off close by the bole. It will be needful, however to be cautious not to inflict too many wounds upon the tree in one season the removing of these therefore, should be the work of two or three years, rather than endanger the health of the plantation. After the removal of these from the boles of the firs and larches, proceed every two or three years, but with a sparing hand, to displace one or perhaps two tiers of the lowermost live branches, as circumstances may direct, being careful to cut close by the trunk, as above noticed. In a plantation of hard wood, under the above circumstances, the trees left for the ultimate crop are not to be pruned so much at first as might otherwise be required only one or two of their competing branches are to be taken away and even these with caution. If it be judged too much for the first operation to remove them entirely, they may be shortened, to prevent the progress of the competition and the remaining parts may be removed in the following season at which time, as before observed they must be cut close by the bole. (*Plant. Kel.* 457.) We cannot agree to that part of these directions which respects the removal of "perhaps two tiers of the lowermost live branches" but, paying great deference to the opinion of Mr Sang we have judged it right, in a work of this nature, to lay it before our readers, and allow them to judge for themselves.

4024. *The operation of thinning and pruning, thickening or filling up or renewing portions that cannot be probably recovered, should thus go on, year after year, as appearances may direct, on the general principles of tree culture; and for this purpose, the attentive observation and reflection of a judicious manager will be worth more than directions which must be given with so much latitude.*

4025. *Farquhar has noticed various errors in Kennedy's Treatise on Planting and even in Sang's Kalendar on the simple subject of distances, which have originated in their giving directions for anticipated cases which had never come within their experience. "Most people," he says "take it for granted, that if trees stand three feet apart, they have only to take out the half to make the distance six feet, though, to do that, they must take down three times as many as they leave. By the same rule, most people would suppose that twelve feet distance was only the double of six; but the square of the latter is only thirty-six, while that of the former is one hundred and forty-four, or four times the latter; so that, to bring six feet distances to twelve, three times must be reserved for every one left. (*Pragmatic Farmer* 226; and *Forest Farmer* 21.)*

4026. *Copse-woods are sometimes improved by turning them into woods, which requires nothing more than a judicious selection and reservation of the strongest of those shoots which proceed from the stools, and which spring more immediately from the collar. But a greater improvement of copse-woods consists in cutting over the overgrown and protuberant stools by the surface of the soil (fig 595 a, b, c, d), which has been found by Montezith completely to regenerate them. The operation is performed with a saw in a slanting direction, and the young shoots, being properly thinned and pruned, soon establish themselves securely on the circumference of large and perhaps rotten-hearted roots. (Forester's Guide, 60)*

4027. *Neglected hedge-row timber may be improved by pruning according to its age. Blake recommends what he calls foreshortening, or cutting in, as the best method*

*both for young and old hedge row timber. This operation is performed by shortening the overluxuriant side-branches (fig 596 a) but not to cut them to a stump, as in snag pruning, on the contrary, the extremity only of the branch should be cut off, and the amputation effected immediately above where an auxiliary side-shoot springs from the branch on which the operation is to be performed (b) this may be at the distance of two, four or any other number of feet from the stem of*

*the tree and suppose the auxiliary branch which is left (when the top of the branch is cut off) is also over-luxuriant, or looks unsightly it should also be shortened at its sub-auxiliary branch, in the same manner as before described. The branches of trees pruned in this manner, are always kept within due bounds they do not extend over the adjoining land, to the injury of the occupier at least not until the stem of the tree rises to a height (out of the reach of pruning when the top branches can do comparatively little injury to the land. By adopting this system of pruning, the bad effects of close pruning on old trees, and snag pruning on young ones, will be avoided, the country will be ornamented, and the community at large, as well as individuals, benefited."*

#### SECT. VII Treatment of Injured and Diseased Trees.

4028. *With respect to wounds bruises casualties, and defects of trees, such small wounds as are required to be made by judicious pruning easily heal up of themselves large wounds, by amputation of branches above six inches in diameter should, if possible, never be made. Even wounds of six inches diameter or under will heal more quickly by the application of any material that excludes the air and preserves the wood from corruption and we agree with Sang in recommending coal-tar or the liquor produced from coals in manufacturing gas. It is, however less favourable to the progress of the bark over the wound than a coating of clay or cow dung covered with moss to keep it moist. Pontey recommends putty and two coats of paint over it. In case the wood at a bruised or amputated place has by neglect become already corrupted, the rotten or dead wood is to be pared out quite into the quick, and the wound is then to be dressed with tar or clay, covered with a piece of mat, sacking, or moss. A wound, hollowed out as above, may at first appear an unsightly blemish but, in subsequent years, nature will lay the coats of wood under the new formed bark thicker at that place, and probably may, in time fill it up to be even with the general surface of the tree.*

4029. *All fractures, by whatever means produced, are to be managed as the circumstances of the case require. If a large branch be broken over at the middle of its length, it should be sawn clear off close by the lateral which is nearest to the bole of the tree but if there is no lateral, or branch capable to carry forward the growth, cut the main or fractured branch in quite to the bole. In both cases, treat the wound as above recommended.*

4030. *Interior rotting, arising from the dampness of the soil, cannot, by the art of man, be cured; though it might have been prevented by timely draining. The hearts of trees frequently rot, where there is no excess of moisture, and especially of such as have been produced from old roots left in the ground by a previous felling. Such roots, when in good ground, send up very great shoots, with few leaves in proportion to their size; from*

the absence of a profusion of these, properly to conduct the juices so abundantly supplied by the roots, the fibre of the wood is loose and imperfect, the next season will produce more leaves in proportion to the supply of juices, yet not a sufficient number for making timber; several years may pass before this event will arrive. This crude and ill-digested timber, disposed to premature decay, is the foundation over which subsequent coatings of wood are laid. yet, however perfect these may be, they do not prevent the progress of decomposition going on in the interior. Nature thus teaches how necessary numerous leaves are to the preparation of the solid wood. the cotyledons and subsequent leaves of a one-year old tree are a thousand times greater compared with its solid contents, than are the leaves to the solid contents of the first year's shoots from roots like the above. *Seng.*

4031. *Shakes often arise from the weight and multiplicity of top branches, and might have been prevented by timely pruning.* Shakes or rents in the boles of trees, however often happen where there is no excess of tops. Sometimes the rain, running down from the branches, wets one part of the bole, while the rest is comparatively dry. If this circumstance is succeeded by an intense frost, before the wetted side becomes dry, the bole may be rent for a length, and perhaps to the depth of the core. Shakes or rents, like the above, are difficult to cure. The best method of helping them is to trace out their upper extremity, caulk it up with oakum, and pitch it over, to prevent the rain descending that way in future. (*Seng.*)

4032. *In cases of hollowiness.* Pontey recommends probing to the bottom, letting out the water if any with an auger drying the cavity with a cloth, filling it with dry sand, plugging it with wood and oakum, and then painting it over.

4033. *Stems or branches decorticated by lightning or otherwise, if the soft wood is not much injured, will heal over and become covered with bark and thus the more certainly and rapidly if the air be excluded by a coating of adhesive matter, as cow-dung and quicklime, or by tying on moss or bandages of mat or cloth.* Pontey gives an instance in which such treatment was successful in the case of an apple tree. (*Pruner* 290.) We have witnessed it on an extensive scale on the trunk of a pear tree and we are informed, on the best authority of other cases now under progress, in the government garden of the Luxembourg, at Paris.

4034. *Withered or decayed tops may arise from age and incipient decay but also, as Pontey states, from improper pruning, or the want of it.* We often see it from the improper pruning of elms, which, after having been close pruned to their summits for many years, are left entirely to nature in that case they branch out luxuriantly below and the top withers. By neglecting to thin out the branches on the stems of non-remous trees the same effect may be produced.

4035. *Stunted bushy tops, on very tall naked stems, show a deficiency of nourishment, from these circumstances, and those on short stems from defects of the soil.* Obliquely placed misshapen heads in detached trees, commonly proceed from the same causes and from want of shelter. Stunted growth, both in tops and stems, is also produced by ivy and by lichens, mosses, mistletoe, and other parasites. Ivy compresses the bark, and precludes its expansion, as well as excludes air and moisture by which the outer bark becomes rigid and corky.—Happily, both men and trees will live a long time under the influence both of deformity and disease.

4036. *Excessive exudations of gum and resins are peculiar to resinous and some other trees when over-pruned, or pruned at improper times.* Mildew honeydew, and blight, three popular names applied to the effects of certain insects of the Aphis kind, attack the oak, beech, poplar, and many trees all that can be said is, if proper regimen has been regularly attended to, trees will overcome these and all other enemies.

4037. *Insects and vermin.* Almost every tree has its particular insect of the Hemipterous and Dipterous families, and many of the Coleoptera are common to all. The foliage of the small-leaved elm of hedges is often almost entirely destroyed in the early part of the season by *Tenthredinidae*, and those of the larch and Scotch pine have suffered materially in some seasons from aphides. The *Aphis larices* L. (*Erroedme* of Leach) increased to an alarming extent, from 1800 to 1809, on the larch, on account of three dry seasons following each other, but, though it retarded their growth, it ultimately destroyed very few trees. *Seng* says, he has known it since 1785 that it dirties more than injures the tree, and is now (1819) thought little of. Indeed, almost every species of tree has been known to have suffered in some one season or more, and in particular districts, from insects; for which, on so large a scale, there seems to be no applicable remedy, but patiently waiting till their excess, or the increase of other vermin their natural enemies, or a change of seasons, causes them to disappear. Trees properly cultivated and managed generally overcome such enemies. The hare is well known to be injurious to young trees, and especially to loblunnas, by gnawing off their bark. Coasting their stems with dung and urine, fresh from the cow-house, is said to be an effectual remedy. It may be put on with a brush to the height of two feet; a barrow-load will suffice for a hundred

trees, with stems of three or four inches in diameter; and its virtue, after being laid on endures at least two years. (*Bull. de Culti. Hort. Mem. iv 190.*)

**BOOK VIII. Products of Trees, and their Preparation for Use or Sale.**

4038. *The ordinary products of trees made use of in the arts are leaves, prunings or spray thinnings, seeds, flexible shoots, bark, branches, roots, and trunks.* Trees also afford sap for wine and sugar, and extract for dyeing; but these products are of too accidental or refined a nature for our present purpose.

4039. *The brush-wood or spray of trees may be turned into charcoal, substituted for thatch in roofing cottages, used as common fuel, formed into fences, or distilled for pyroligneous acid.* Some sorts, also, as the spray of the oak, the willow the birch, the mountain ash, and others, may be used in tanning. In a green state with the leaves on, the spray of the elm, the poplar, the lime, and others, may be used in feeding cattle or the spray may be dried like hay, and stacked for that purpose, as in Sweden or it may be rotted for manure. The spray of all trees not resinous may be used in the distillation of pyroligneous acid. This acid is much used in calico-printing works and, according to Montath, sold in 1818, in the neighbourhood of Glasgow, at from 17 2s to 14 10s per ton. The distillation is carried on in a cast or malleable iron boiler (*fig 597*), which should be from five to seven feet long, three feet wide, and

may four feet deep from the top of the arch, built with fire-brick. The wood is split or round not more than three inches square in thickness, and of any length so as to go into the boiler at the door. When full, the boiler door (*b*) is properly secured, to keep in the steam then the fire is put to it in the furnace below and the liquid comes off in the pipe above (*d*) which is condensed in a worm, in a stand (*e*) filled with cold water by a spout (*f*), and empties itself first into a gutter below (*g*), and from that it is let into barrels, or any other vessel and thus the liquid is prepared. One English ton weight of any wood, or refuse of oak, will make upwards of eighty gallons of the liquid. There is also a quantity of tar extracted, which may be useful in ship-building (*Gard. Mag. vol. II.*)

4040. *The thinnings*, when not beyond a suitable age, and taken up properly and at a proper season, may be planted in other situations, or as single trees and groups or they may be used as hoops, hop-poles, poles for garden training, for fencing, for props in celleries and for a great variety of purposes those of which the bark is useful for tanning should not be cut down or rooted up till May, but the others at any time during winter. It is common to sort them into lots, according to their kind or use; and so faggot up the spray for fuel, besom stuff, or for distilling for bleachers' liquid.

4041 *The seeds of trees in general cannot be considered of much use beyond that of containing the species.* The seeds of the oak, beech, and sweet chestnut, however, are valuable for feeding swine, and where they abound may either be swept together after they drop, and carried away and preserved dry in lots or cellars for that purpose; or, if other circumstances are favourable, swine may be driven under the trees to collect them. These and other seeds, as the haw and holly, are eaten by deer. The seeds of the trees mentioned, and of all the resinous tribe, are in general demanded by the nurserymen, for the purposes of propagation, and the seeds of almost all other trees and shrubs are in limited or occasional demand; they may also be collected for private sowing. These seeds generally ripen late in the season, and are to be collected in the end of autumn or

beginning of winter, with the exception of a few, such as the elm, poplar, willow, and one or two others, which ripen their seeds in May and June.

4042. In oak grounds, willows produce flexible shoots, and, whether intended for the basket-maker or cooper, should not be cut till the second season after planting, in order to strengthen the stools; but by the third autumn the crop will be fit for the basket-maker; and in the fourth, plantations intended for the cooper (hoops requiring the growth of two years) will be ready. The seasons for cutting are November and March, after the former period the wounds are apt to be injured by frost, and after the latter the sap is too far advanced, some is lost by bleeding, and the buds are developed too suddenly to admit of proper strength in the shoots. The cut should be made within three buds of the point whence the shoot issued, in a sloping direction, and the section on the underside. In cutting hoop-willows, the swell at the bottom of the shoot only should be left, that being furnished with abundance of buds for future growth. After being cut, the hoops are trimmed from any side-shoots, and tied up in bundles of a hundred, of six scores each, which, in 1890, sold for from four shillings to five shillings a bundle. The willows are sorted into three sizes and tied in bundles two feet in circumference, within a foot of the lower ends. When to be peeled, they are immediately after cutting set on their thick ends in standing water, a few inches deep, and there they remain till the sap ascends freely which is commonly by the end of the succeeding May. "The apparatus for peeling is simply two round rods of iron, nearly half an inch thick, sixteen inches long, and tapering a little upwards, wedged together at the one end which is sharpened, so as that it may be easily thrust down into the ground. When thus placed in a piece of firm ground, the peeler sets down opposite to it, and takes the willow in the right hand by the small end, and puts a foot or more of the great end into the instrument, the prongs of which he presses together with the left hand, and with the right draws the willow towards him, by which operation the bark will at once be separated from the wood the small end is then treated in the same manner, and the peeling is completed. Good willows, peeled in the above manner, have been sold, for some seasons past, at from six shillings and sixpence to seven shillings the bundle of four feet in circumference. After being peeled, they will keep in good condition for a long time, till a proper market be found."

4043. *Copse-woods* are generally cut over when the shoots of the stools have attained from three to five inches' diameter at their bases, some grown chiefly for hop-poles, and ware or stuff for crates, hampers, or wickered hurdles, are cut over earlier; and others, where small timber for fencing and other country purposes is wanted, are left later. In some parts of Herefordshire, where the oak grows with great rapidity, copse-woods are cut over every twelve years, in the highlands of Scotland, where it grows much more slowly, the time varies from twenty-five or thirty years. "The bark is there considered as having arrived at its utmost perfection and at its highest value, at the age of between twenty and thirty years. Under that age, its virtues are weak; above it, the bark becomes coarse, and loses its sap. Another important reason for cutting down oak coppice-wood about the above period is suggested in the *Swilshire Report*, p. 218., namely, "that it is a fact established by experience, that it will not renew itself, if it remains uncut beyond the space of about forty years." (*Gen. Rep. of Scotland*, 218.) Where there is a considerable tract of copse-wood, it is common to divide it into portions, in number according to the period of cutting. These are to be cut in rotation, so that, when the last portion is cut over, the first is again ready for cutting.

4044. The seasons for cutting the kinds of trees whose barks are not made use of are winter and early in spring; but the oak and other trees which are peeled, are left till the middle of April or May. Birch and larch woods will peel nearly a month earlier than the oak. Should there be no frost, birch and larch may be peeled about the beginning of April, but the birch is commonly allowed to stand till July and the peeling of it is commenced after that of the oak has been completed. The reason is, there is an outer skin upon birch-bark which requires to be taken off as it is of no use to the tanner and renders that part which is of use more difficult to be ground; the month of July is the only time at which the two barks can be separated with ease, as at this time the juice or sap has made its circulation through the tree and bark, and this circumstance renders the separation more easy. From the beginning of May to the middle of July is the usual time for barking the oak. The earlier in the spring this operation is performed on the oak, both for the growth of a natural wood, and for the bark the better. When the sap has begun to rise, the bark will easily be detached from the wood and it can be taken off without loss of time; and, if the whole could be taken off before the leaf is completely developed, the bark would be better. After the sap has risen to the leaf and new growth, the bark becomes more dry and separate more readily to separate it from the wood; and when what is called the black sap is descending the tree, the bark taken off is black, and loses its original colour; at this time also the bark begins to decay off a sort, more especially young bark without much work on it; this outer skin having lost of the proper sap or juice, and being much drier when taken off, will make less, and consequently will not be so valuable. If possible, oaks should be barked by the middle of June, as every ton of bark taken off after the first of July will be deficient two or three tons, compared with the same quantity taken off in May or early in June.

4045. The determination of cutting is generally fixed for the eleventh day of July and after this date there should not be a single acre of oak wood-cutting intended for the growth; and as soon as possible after the eleventh, the chips of the wood and bark should be carried away, that the young growths may not be damaged or injured, as at that time they will have made considerable progress; at any rate, these should neither be wood nor bark remaining within the new cut hag after the first of August.

nor should either become cart be permitted to enter it after that period; for, after the beginning of August, only timber which is termed a *Lammest growth*, and the future prosperity and health of the copse in a great measure depend on the first year's growth, as far as regards form and vigour of the shoots. (*Forester's Guide*, 55.)

4044. The best mode of cutting is evidently that of using a saw, and cutting the shoots over in a slanting direction close by the surface. When the stool, after having been cut several times, has acquired considerable diameter it is customary in the midland counties, *Mosses* states, to hollow it out in the centre, from a notion that by getting away the central roots, the circumferential stems will grow more vigorously and become as it were separate plants. This is in fact the case in very old copses. For several cuttings, however it must evidently be the safer policy to keep the stool highest in the middle to throw off the rain, and preserve it sound.

4045. *Mosses* says, "It will be found, upon experiment, perfectly evident, that stools dressed down to the surface of the ground (taking care always not to loosen the bark from the root, or allow it to be peeled off in the smallest degree below the earth but rounded down level to it) will send forth the most vigorous shoots, and stand the weather and be the stoutest and best throughout the age of the coppice." (*Forester's Guide*, 61.) From the late season at which the trees to be barked are generally cut, they often receive considerable injury both from that circumstance, and the manner in which the operation is performed. Monthly appears to us to have furnished the best directions for executing the work in a safe manner. He first sends a person furnished with an instrument with a sharp cutting edge (*fig.* 593. a) through the copse, whose business is, "to trample down the long grass or faggots all round the root, and then to make a circular incision into the bark so deep as to reach the wood at about an inch above the surface of the earth thus the bark when taken off, will injure no part of that which is below the circular incision."

4046. The root of the tree being first prepared, the cutters ought to proceed to their part of the work, not with an axe, however, as is most generally recommended, but with a saw; because, in cutting with the axe, unless the root of the tree is so small in diameter as to be severed in one or two strokes at most, the axe loosens the root to such a degree, that it not only loses the present year's growth, but often kills altogether to grow. Therefore, if the diameter of the root be six inches, or upwards, it should always be cut with a cross-cut saw entering the saw about half an inch above where the circular incision has been made into the bark. If a small tree; but if the tree be ten or twelve, or more inches in diameter the saw ought to be entered two inches above it.

4047. There are two advantages to be derived from cutting with the saw. It has no tendency to loosen the root of the tree, but leaves it in such a condition as to be more easily and properly dressed; it also saves a portion of the wood that would otherwise be destroyed by the axe. On no pretence should cuts of six inches diameter be cut with an axe, but always with a saw. Having cut through the tree with a saw take a sharp adze and round the edges of the stool or root, going close down to the surface of the earth, taking with the adze both bark and wood, sloping it up towards the centre of the stool, taking particular care always that the bark and wood both slope alike, as if they formed one solid body, being sure always that the bark be not detached from the root. An objection has been made to this mode of cutting with the saw as taking up too much time; but I have found that two men with a cross-cut saw kept in good order will cut as much as two men will with an axe. (*Forester's Guide*, 66.)

4048. In the operation of barking trees, "the barkers are each furnished with light short-handled mallets, made of hard wood, about eight or nine inches long, three inches square at the head, and the other end sharpened like a wedge, in order the more easily to make an incision in the bark, which is done all along the side of the tree which happens to be unpeeled. In a straight line and at two barkers are generally employed at one tree, it is proper that whilst the one is employed in making an incision with the mallet, as above, the other being furnished with the barking-kill (*fig.* 594. a) cuts the bark across the tree, in lengths of from two feet six inches to three feet. Having thus made the incision in the bark, both ways, the barkers are being also each furnished with peeling irons of different sorts (*b, c, d, e*); if the tree or piece of timber to be barked is such as the two barkers can easily lift one end of it,

it is placed on two pieces of wood three feet long and called horses, these are about the thickness of a paling-stake and have a forked end on each about six inches long the other end being sharpened to go into the ground two of these horses are placed in a triangular form against one another one end of the piece to be peeled being raised on the horses, the two barkers standing opposite to each other, and using the peeling iron into the incision made by the mallet, and pressing the iron downwards between the bark and the timber. In this way it will be found very easy to take the bark off in one whole piece round the tree, and, if possible, let these pieces be as long as the incisions made in the bark. In some cases where there is not much sap, the bark may require a little heating with the square end of the mallet, to cause it to separate easily from the wood but the less heating with the mallet the better as it has a tendency to blacken the bark in the inside or fleshy part of it, so that, when the tanner uses it, he ruins it to be damaged, and undervalues it. The branches of the tree being previously all lopped off with the axe, the persons, in number according to the extent of the work, with the bill smooth all the branches, cutting them in lengths of from two feet six inches to three feet, down as small as one inch in circumference. The barkers, principally women, are each provided with a smooth hard stone of about six or eight pounds weight, beside which they sit down and having collected a quantity of saplings, branches, or twigs, they hold the piece on the stone with one hand, and with the mallet in the other, they bark it till the bark be split from the wood, from the one end to the other and taking it off all the length of the piece, if possible, then lay it regularly aside, till a bundle of considerable size is formed.

4049. Drying the bark. The point most particularly to be observed in this art is, putting the bark up to dry; which is done by setting it upon what are called the lotts or ranges. These are erected by taking forked pieces of the lopping, called horses, the one three feet long, the other two feet six inches, and driving them about four inches into the ground, opposite one another, about two feet asunder in the breadth and as much betwixt them lengthways as will admit long small pieces of wood to be put upon them, and as many of these must be put together as will hold the bark of every day's peeling. These ought to be erected in as dry and elevated a spot as can be found in the margin of the wood, or better on its outside. The bark being carried and laid on this lot, with the thick side of it all laid to the high side of the range, and the small bark laid on to the thickness of about six inches; and the bark taken off the largest of the wood laid regularly on the top, which serves for a covering, and the lotts or ranges having a flexibility of about six inches, the rain will run off them readily and if properly put up in this manner, they will keep out a great deal of rain. After it has lain in this state for three days, if the weather is good

and dry, it ought to be all turned over, and the small bark spread out, so as not to allow it to sit together, which, if much pressed, it is apt to do; and if it does so with the natural sap in it, it has a chance of moulding, which is extremely detrimental to the bark, and both lessen it in weight and in value. After the bark has stood on the ground about eight or ten days, if the weather be good, it may either be put into a heap or a stack, or if intended to be put up into a stack it may now be done. A stack of bark ought never to exceed eight feet in width, and twelve or fifteen feet in height, raised in the middle like a haystack. If it is to stand any length of time in the stack, it ought to be thatched, and in that state may remain all winter. The greatest care ought to be taken to preserve the colour of the inner parts of the bark, because the colour of it is generally looked to as a principal criterion of its value. Before being put into the stack, the outside sap ought to be dried out of it, in order to prevent its fermenting; because, if a fermentation takes place in one part of the stack, it generally goes through and spoils the whole. The same mode of treatment will do for all kinds of bark as well as the oak; but the birch has an outer or shagreened skin upon it, that is rejected by the tanner and, as already observed, must be peeled off.

4034. *Chipping the bark.* "When the bark is ready for the tanner it has to undergo the work of chipping, which is done by driving in two or more stakes into the ground, with a fork on the upper end of each, leaving them about two feet six inches from the ground, and laying a long small piece of wood across between the two, where a number of people stand, and the bark is carried and laid down behind them, which they take up in their hands and lay on the cross tree, and then, with a sharp whittle or knife in the other hand, they cut it into small pieces, about three inches in length; when this is done, it is trampled into heaps, which hold about two hundred weight each, and in these bags it is weighed when sold by the ton, in tons, hundred weights, quarters, and pounds, and in the above manner delivered to the merchant or tanner." (*Forester's Guide*, 198.)

4035. *The disburied timber* is prepared for sale by being sorted into straight poles of the largest size, stakes and other pieces fit for palings, faggots, fuel, &c. The unburied wood is similarly sorted, and a faggot, where there is much bark or ash, cord wood or bundles of stems shorter for making pecking crates, hampers, &c. poles for hops, larger poles for fences, rails, paling-stakes, stakes and stools for hurdles, beam-stuff, spars for distillation, and a variety of other objects, according to the local demand or the opportunity of supplying a distant market by land-carriage. The brush or spray of non-resinous trees is called in some places *tan-wood*, and is used for distilling the pyroligneous acid used in bleach fields and other print-works. "When wood of this description is sent to Glasgow where there are extensive works for the purpose of distilling it, it sells readily at from 1*l.* 5*s.* to 1*l.* 10*s.* per ton; but when there are large outtings, particularly of young woods, it is worth while to erect boilers near the wood to distil it, as these boilers can be erected at no great expense, and in this case the liquid is easily carried in casks to where it is consumed, at less expense than the rough timber could be of course it will pay much better. Hard wood of this description is also used for charcoal, but in distilling it, there is part of it made into charcoal, which will supply the demand of that article, so that it is by far the most profitable way when there is any great quantity to dispose of to erect boilers and distil it. Unless where the local situation of the wood will admit of its being shipped at a small expense and carried to where the works mentioned are carried on. All kinds of non-resinous woods will give the extract in question; but oak, ash, Spanish chestnut, and birch, are the best." (*Forester's Guide*, 155.) Where the oak grows slowly as in the Highlands, the butt-ends of the poles are used for stakes for chaise wheels. "Long spikes are from thirty to thirty-two inches long by three inches and a half broad and one inch and a half thick, and the short ones for the same purpose, from twenty-two to twenty-four inches long, and the same size otherwise. Cart-wheel spokes, from twenty-six to twenty-eight inches long, four inches broad by two inches thick. These are the sizes they require to stand when rough barked from the axe. Small wood, when sold for this purpose, brought, in 1830 5*s.* a cubic foot, measured down to three inches square." (*Ibid.*, 156.)

4036. *In some cases open-steads are sown with grass-seeds and pastured by sheep, horses, and cattle.* Some admit the animals the fifth year after the last cutting others, not till the eighth but Monteith thinks this should never be done till the fifteenth year. If the ground is properly covered with trees, it can seldom be advantageous to admit any species of stock, unless during a month or two in winter.

4037. *Pollard-trees*, which may be considered in most cases as injurious deformities, are lopped at stated periods i.e. copse-woods, and the lop, whether to be barked or otherwise, is to be treated in all respects like that of copse.

4038. *The period at which trees are felled*, for the sake of their timber, is determined by various causes. By maturity of growth, or where the annual increase is so trifling as to render their standing no longer worth while in point of profit, when wanted for private use or sale or when defects in the tree, or new arrangements in its situation, point out the necessity of its removal. "A timbered estate, Marahal observes, 'should frequently be gone over by some person of judgment, who, let the price and demand for timber be what they may ought to mark every tree which wears the appearance of decay. If the demand be brisk, and the price high, he ought to go two steps farther and mark not only such as are full-grown, but such also as are near perfection. In trees, as in the human species, there are three stages, youth, manhood, and old age. In the period of youth, the growth is rapid, in manhood, that growth is matured and in old age, it begins to decay

4039. *The most profitable season for felling timber* is at what may thus be termed the beginning of manhood. After that time, though the tree may appear sound and healthy, its annual increase is so little, that it would be more profitable to cut it down and replant. The number of years that a tree may stand, before it arrives at this period, must vary in different soils and situations; but the period itself may easily be ascertained by the annual shoots, the state of the bark, and by taking the circumference of the tree at the same place for two or three successive seasons, and comparing the difference. In the view of profiting from timber production it is of great consequence to cut down plantations at maturity. Many trees will stand half a century or more, and when they are full-grown appear quite healthy, and at the same time make little or no increase of timber. But there are particular cases, arising from the nature and state of the soil, where it may even be more profitable to cut timber before it is arrived at a full growth. (*Trans. of Conn. Soc. A. 1771*)

4040. *Preparation for felling.* It has been strongly recommended to disburk trees a year or more before they are felled down, in consequence of the result of certain experiments commenced by Buffon in 1732. In May of that year, he disburked three oak trees, fifty feet in height, where they stood. In the space of three years they died, and, on cutting them down, the outer wood was found hard and dry, and the inner wood moist and soft. After trying the strength, &c., he concludes that "timber which has been disburked and dried whilst standing, will yield timber and grow stronger than timber cut in its bark." These are other French practices in forest management. (*Trans. of Conn. Soc. A. 1771*)

strongly recommended this practice, which is followed in some places on the Continent, and in this country

with the oak and larch; but not, as far as we have learned, with any other tree. Montebell finds it to be the most efficient way of seasoning larch timber. He barked some trees in spring, and did not cut them down till autumn, and others stood in the peeled state for two years. After various and extensive trials, he is "decidedly of opinion that the larch treated in this way at thirty years of age will be found equally durable with a tree cut down at the age of fifty years, and treated in the ordinary way" (*Forester's Guide*, 182.)

4060. *As the dry rot* (*Mercillius lichrymans Schum.*) is found to arise in a great measure from want of seasoning, or at least to proceed with the greatest rapidity in timber not well seasoned, this practice seems to deserve adoption in that point of view (*Engl. Dict. Suppl. art. Dry Rot*). In some parts of the north of Europe, the trees are disected of their bark for a foot or two feet in height from the ground a year or more previous to that on which they are to be killed. We saw this done in Poland and Lithuania; but, though we made diligent enquiry there and in Sweden, we could not learn distinctly the extent to which it was practised in the latter country and Norway. It is occasionally practised in Finland, for the valuable purpose of hardening the soft wood; but also accompanied by a deep incision made for the purpose of extracting tar; a practice evidently injurious to the timber and therefore generally in these countries, kept out of view. When trees stand close together, a very obvious preparation for felling is lightening the tops of such branches as would, in falling, do injury to the trees that are to be left, or to other adjacent objects.

4061. The season of felling is commonly winter for timber not to be disbarked; but some, for the resinous tribes, recommend summer as being the season in which it is generally felled in the north of Europe and in the Alps. But the summer season is there adopted from necessity as in winter the woods are so filled up with snow that felling is hardly practicable. As the timber of these countries is generally squared for the market, the soft wood is chiefly removed, so that the season of felling does not seem to have to be of much consequence. Besides, the timber is never so full of sap in summer as it is in spring and autumn, and therefore, next to midwinter midsummer may be the best time for felling all kinds of timber trees. Where the trees are disbarked at the base a year or more before felling, the soft wood will be partially hardened, but this practice is by no means general in the North.

4062. As some is a recent work on preserving the British navy on dry rot, &c. after collecting the opinions of all the ancient and modern authors who have written on felling timber concludes that the common notion that trees felled in winter contain less of sap or of the vegetable juices, than those cut down at any other season of the year, is not true, and that the method of barking standing trees in spring and not barking them till the succeeding winter has not in any way realized the expectations formed of the plan. After describing all the modes that have been adopted for seasoning timber he concludes that the best is to "keep it in air, neither very dry nor very moist; and to protect it from the sun and rain by a roof raised sufficiently high over it, so as to prevent, by this and other means, a rapid evaporation of air" (*Inquiry into the Means of preserving the British Navy from Dry Rot &c. by Knowles, Sec. to the Com. of Surveyors*, chap. iii.)

4063. The operation of felling is performed either by digging an excavation round the stem, and cutting the roots at two or three feet in distance from it, or by cutting over the stem at the surface. By the former mode the root is obtained firmer for use, and the ground more effectually cleared and prepared for the roots of adjoining trees or whatever crop is to follow. Where the tree is intended to stoil, which can very seldom be advisable in the case of cutting full grown timber or where there is some nicely regulated tree to fall against it, down, so as not to injure other trees or adjoining objects, it is cut or sawn over, and the root, if to be removed, dug out afterwards. In cutting large trees, in order to make the tree fall the way required, either the cross-cut saw on that side of the tree it is intended to fall and cut it about a third part through, then enter the saw at the other side, and when it is cut so far as to admit a wedge, place the wedge exactly opposite to the way you want the tree to fall, and keep driving it slowly till the tree is nearly cut through. (*Montebell*.) The tree, being felled is next disarmed of its branches, which are sorted into fence wood, fuel, ton wood, &c. according to the kind of tree and the trunk is generally preserved as entire as possible for the purchaser. Sometimes it is cut in two, and the root-cut, or butt-end, being the most valuable, sold for one class of purposes at a higher price, and the top-cut for others somewhat lower.

4064. The seasoning of timber consists in evaporating the fluid matter or sap by the natural warmth of the atmosphere, with the precaution of screening the timber both from the direct action of the sun and wind, otherwise it cracks, and receives much injury. As this process proceeds slowly and irregularly when conducted in the ordinary way Mr. Langton has discovered a new method of seasoning timber, consisting in the removal of the greater part of the atmospheric pressure, and the application of artificial heat, by which the time necessary to season green timber and render it fit for use, is only about twice as many weeks as the ordinary process requires years. In this process the power of an air pump is added to draw the sap out of the interior of the wood and the tendency of the fluid to the outside being thus increased, a higher temperature than that of the atmosphere can be applied with less risk of causing the timber to split. Consequently the process may be completed in less time, and a few trials will show the best relation between the heat and heat for the different kinds of wood. The late Mr. Tredgold's opinion being asked by him gave it as decidedly in favour of Mr. Langton's process and timber is now completely seasoned by Mr. Langton in eight or ten weeks after the tree is cut down (*Newton's Journal*, vol. i. 2d series, p. 145.)

4065. *Seasoning timber by steeping* "Some remarkable facts respecting the durability that may be given to timber by artificial means have been observed at Clonsburn. The proprietor of that estate has, for thirty years, been in the constant practice of soaking all fir and larch timber after it is sawed into planks in a pond or stream of water strongly impregnated with lime. In consequence of this soaking the saccharine matter in the wood on which the worm is believed to live, is either altogether changed, or completely destroyed. Scotch fir wood, employed in roofing houses, and other indoor work, treated in this manner has stood in such situations for thirty years, sound and without the vestige of a worm. In a very few years fir timber so employed, without such preparation, would be eaten through by that insect. (*Montebell of Clonsburn, in Edin. New Phil. Journ.* June, 1823.)

4066. The roots of trees are the last product we shall mention. These should, in almost every case, be effectually eradicated to aid in which, in the case of very large roots, splitting by wedges, rifting by gunpowder tearing up by the hydrostatic press, or by a common lever, may be resorted to. Some compact ash or oak roots are occasionally in demand by smiths, leather cutters, and others but, in general, roots should be reduced to pieces not exceeding three feet long, and six inches in diameter, and put up in stacks not less than three feet every way, but commonly containing two cubic yards. These, when dry, are split for fuel, or reduced to charcoal on the spot. In eradication and stacking up coppice-woods it is common to allow a certain sum per stack, and something for every acre of ground cleared if there are no trees to bark, allowances are also made for the poles, faggots, &c., so that no part of the operation is performed by day work.

4067. The usual method of charring wood is as follows.—The wood being collected near the place intended for the operation, and cut into billets, generally about three feet

in length, the pits or stacks are usually formed in this manner. — A spot adapted to the purpose, of from about fifteen or twenty feet in diameter of a conical form, is selected, and after being properly levelled, a large billet of wood, split across at one end, and pointed at the other, is fixed in the centre of the area, with its pointed extremity in the earth, and two pieces of wood, inserted through the clefts of the other end, forming four right angles; against these cross-pieces, four other billets of wood are placed, one end on the ground, and the other leaning against the angles. A number of large and straight billets are afterwards laid on the ground, to form a floor, each being, as it were, the radius of the circular area; on this floor, a proper quantity of brush or small wood is strewed, to fill up the interstices, when the floor will be complete and in order to keep the billets in the same position in which they were first arranged, pegs or stumps are driven into the ground, in the circumference of the circle, about a foot distant from one another, upon this floor a stage is built, with billets set upon one end, somewhat inclining towards the central billet, and on the tops of these another floor is laid, in a horizontal direction, but of shorter billets, as the whole is intended, when finished, to form a cone. The pile is then covered over with turf, and the surface generally plastered with a mixture of earth and charcoal dust.

4067. *Previously to the operation of setting fire to the pile, the central billet in the upper stage is drawn out, and pieces of dry combustible wood substituted in its place, to which the fire is applied.* Great attention is necessary during the process, in the proper management of the fire, and in immediately covering up the apertures through which the flame protrudes itself, until the operation be concluded, which is generally effected in the space of two or three days, according to circumstances. When the charcoal is thought to be sufficiently burnt, which is easily known from the appearance of the smoke, and the flames no longer issuing with impetuosity through the vents, all the apertures are to be closed up very carefully with a mixture of earth and charcoal dust, which, by excluding all access of the external air, prevents the coal from being any further consumed, and the fire goes out of itself. In this condition it is suffered to remain, till the whole is sufficiently cooled, when the cover is removed, and the charcoal is taken away. If the whole process is skilfully managed, the coals will exactly retain the figure of the pieces of wood some are said to have been so dexterous as to char an arrow without altering even the figure of the feather (*Encyc. Brit.* vol. v. art. *Charcoal*.)

4068. *The method of charring wood, for the making of gunpowder according to an improved system, adopted not many years ago, is however a much more costly operation though the expense attending it is amply compensated by the superior excellence of the article when manufactured.* It is done in iron cylinders, and in so complete a manner that every particle of the wood is charred. The oily or tarry matter is also preserved, and may so far as the quantity goes, be made use of instead of foreign tar or pitch. This mode of charring wood for making gunpowder is carried to the greatest perfection near Faversham in Sussex, and there is a manufacture of a similar nature near Chester. (*Gen. Rep. for Scotland*, vol. II. p. 362.)

#### SECT. IX. *Estimating the Value of Plantations and their Products, and exposing them to Sale.*

4069. *The valuation of timber forms a distinct profession, and can only be acquired by continued observation and experience.* like other valuations of property, it depends on a great variety of considerations, some of a general but the greater part of a local nature. We have already offered some remarks on valuing young plantations, as a part of what may be called the inherent value of landed estates (8850.), and shall here confine ourselves to the valuation of saleable trees.

4070. *In valuing saleable trees of any kind, their number per acre or their total number by enumeration being ascertained, and the kinds and sizes classed, then each class is to be estimated according to its worth as timber fence-wood, fuel, bark &c.*

4071. *In a coppice wood which cannot readily be measured,* "the readiest method of counting the stools is, to cause two men to take a line, say about a hundred feet long or more and pass it round as many of the stools as it will enclose, the one man standing while the other moves round a new number of stools then count always the stools betwixt the two lines causing the one man to move while the other stands still, and so on alternately. The valuator at the same time taking care to average every twenty stools as they go on, before losing sight of the counted stools. This way too, is a very speedy and sure method of counting the number of trees in any plantation."

4072. *Or the stools of a coppice wood may be counted and averaged* "by two men going parallel to each other, and the person valuing going betwixt them the two men putting up marks with moss, or pieces of white paper, on a branch of the stools; the one man always going back by the last laid marks, and the valuator always counting and averaging the stools betwixt the newly laid and the last made marks; counting and averaging the stools always as the men go on, taking only twenty or even ten stools at a time. To those who have been in the practice of doing this frequently it will be found very easy, and will be done very quickly, and with a very considerable degree of accuracy. The proper method of learning to do this correctly is, when a person cuts an oak wood for the first time (or even when the work is repeated several times); he should then, in order to make himself perfectly acquainted with ascertaining the quantity of bark that a stool, or even the stump of a stool, will produce, go before the process, and select a stool or stump; after having examined it narrowly he supposes it to produce a certain quantity of bark, and marks this down in his memorandum book. He then causes a person to peel it by hand, dry it, and carefully tie it up and weigh it, and compare it with the weight he supposed it would produce, and he will at once see how far his calculation approaches the truth. A stem of oak, from a natural shoot, suppose it to measure in girth five inches, by seven feet long, will contain two solid inches, and one third of an inch, according to the measurement of Hoppus. This stem or shoot will produce two pounds two ounces of bark. Again, a stem or shoot of natural oak, measuring four inches in

girth, by nine feet in length, will be found to contain one solid foot of wood, and will produce thirteen pounds and a half of bark." (*Forrester's Guide*, 170.)

4073. *When growing trees are valued*, an allowance is made from their cubic contents for the bark. The rule given by Montcuth is, "When the girth or circumference is any thing from twelve inches up to twenty-four inches, then deduct two inches; from twenty-four to thirty-six, three inches; from thirty-six to forty-eight, four inches; from forty-eight to seventy-two, five inches; and above seventy-two, six inches. These deductions," he says, "will be found to answer in almost all trees, unless in such as are very old, and have rough and corky barks, or barks covered with moss, when an extra allowance is to be made." (*Forrester's Guide*, 180.)

4074. *In valuing measurable oak-trees*, many persons proceed on the data that every cubic foot of timber will produce a stone (sixteen pounds) of bark. "This," Montcuth says, "is not always correct;" and he states the following facts from his own experience, with a view to assist beginners in ascertaining the quantity of bark from different trees. "An oak-tree, about forty years old, measured down to four inches and a half as the side of the square, and weighing only the bark peeled off the timber that is measured, without including the bark of the spray, &c., every foot of measured timber will produce from nine to eleven pounds of bark. An oak-tree of eighty years old, weighing only the bark peeled off the measurable timber, as above, every foot will produce from ten to thirteen pounds of bark. Every foot of large larch timber, peeled as above, will produce fourteen pounds of bark. Every foot of mountain-ash, as above, will produce eleven pounds and a half of bark. Every foot of the willow unless a very old one, will produce from nine to eleven pounds of bark. Every foot of larch fir, not exceeding thirty years old, will produce from seven to nine pounds of bark. The bark of trees, particularly the oak, is peeled off, every branch and shoot, down as small as an inch in circumference." (*Forrester's Guide*, 189.)

4075. *To facilitate the measuring of standing timber* various ingenious instruments and machines have been invented, by Montcuth, Gorrie, Rogers, and others. Perhaps the most generally useful is Broad's callipers (fig. 599). This instrument is composed of two thin pieces of deal about thirteen feet long, with

599

a brass link or index (c), on which are engraven figures denoting the quarter girth in feet and inches. Raising the instrument, the index end (c) is taken hold of, and the other applied to that part of the trunk where the girth is to be taken; opening it so wide as just to touch at the same time both sides of it, keeping the graduated index uppermost, on which the quarter girth will be shown allowing one inch in thirteen

600

for the bark. For taking the height of a tree, rods of deal or bamboo, seven feet long, made so as to fit into scurles at the end of each other tapering as in a fishing-rod, may be used. Five of them with feet marked on them would enable a man quickly to measure the height of a trunk of more than fifty feet as he would reach above seven feet. Montcuth's machine being described in the *Encyclopædia of Gardening* (2d edit. § 8270) and Gorrie's in the *Gard. Mag.* (vol. ii. p. 9), we shall here confine ourselves to the invention of Mr. Rogers.

4076. *Rogers's clinometer* (fig. 600) consists of a tripod stand, and a machine for taking angles horizontally as well as vertically. An upright stem arises from the top plate, at the end of which is a ball, with a hole perforated through it, to receive the horizontal stem of the instrument; &c. may be called the lower limb of the instrument, which is to be placed in a truly horizontal position, and adjusted by the suspended level (b). The limb (c) rises on a joint at c, and slides upon a vertical arch (f) which is graduated. At the joint (e) there is an eye-piece, through which the surveyor looks along the side of the bar (h) to a small point, or rising edge, at the end of the bar (the part of the tree cut by this line of observation will, if the instrument is properly adjusted, be perfectly horizontal with the eye-piece. An eye-piece is also placed at d, on the upper

side of the rising limb, for the purpose of looking along this limb to a point or rising edge (*f*) in its extremity. The surveyor elevates this limb, until that part of the tree intended to be noticed is exactly cut by the line of observation, and then angle contained between that and the horizontal is shown upon the divided arch (*f*). It is here to be observed, that the graduations upon the arch (*f*) are not angles of elevation, but scales or graduations answering to feet and inches of a tangent line extending from the horizontal point upwards, taken at a given distance from the tree; consequently, there are two or more trees of divisions, answering to the several distances at which the instrument may be planted. Twenty feet first and thirty-eight feet are supposed distances, and the graduations upon the arch (*f*) are made accordingly. For lofty trees, the sliding diameter is often used; but for shorter trees, the distance of twenty feet will be sufficient. The horizontal scale which is to determine the diameter of the trunk, at the several points of observation, are intersected by the limb (*g*), which slides laterally upon an arch or graduated plate (*h*) divided upon the same principle as the arch (*f*). The limbs (*h*) or (*g*) being fixed, so as to coincide with one side of the trunk, the limb (*g*) is then moved until it coincides with the other side of the trunk, and the scale extended between the two points, by the graduated plate (*h*), the diameter in feet and inches of the trunk at the points of observation. The length of the trunk, and the diameter in the several parts, being thus ascertained by the improved instrument, recourse must then be had to tables, calculations, or the ordinary sliding rule, for the purpose of obtaining from these advancements, the solid content of timber in each portion of the tree. There are adjusting screws, and cylindrical racks and pinions for moving the limbs of the instrument, and altering their position, as circumstances may require and when erected arms, or best parts of the trunk present themselves, the instrument may be turned upon its side in the butt of the top of the stem (*e*) and used in an inclined position. (*Newcomen's Jour.* vol. ix. p. 363.)

4077 *The price of timber*, like that of every other article in general use, varies with the supply and demand, and is easily ascertained from the timber-merchants at the different sea-ports; as is that of bark, charcoal, and fire-wood, from the tanners and coal-merchants.

4078. *The usual modes of disposing of timber trees* are, selling the trees standing, by auction, by receiving written proposals, or by bargain and sale 2d, cutting down the trees, and selling them in the rough, by either of these methods 3d, converting the fallen trees that is, cutting them up into the planks or pieces to which they are best adapted, or which are most eligible in the given situation. The first method seems the best, especially on a large scale, and also for the disposal of copse wood or deer crops.

## CHAP. X

### *Formation and Management of Orchards.*

4079. *The formation of orchards* is to be considered among the permanent improvements of an estate; and should be kept in view in its first arrangement or laying out. No temporary occupier could afford to plant an orchard without extraordinary encouragement from his landlord. Orchards in this respect may be ranked with timber plantations, and both subjects together agree in belonging equally to agriculture and gardening. Orchards have doubtless existed in Britain for many ages as appendages to wealthy religious establishments, but, as objects of husbandry or field culture, they do not appear to have been adopted till about the beginning of the seventeenth century (*Lawson*.) They were then introduced by Lord Scudamore in Herefordshire, in which county and in such parts of those adjoining as exhibit a red marly soil, are the best fruit orchards in England. The chief produce of these orchards is cider and perry; but as these liquors are not in very general demand in this country, and are confessedly less wholesome and nourishing than malt liquors, their formation cannot be carried to any great extent. It seems desirable, however, that orchards of moderate size should be as generally introduced as possible; as the use of the fruit in pies, tarts, and sauces would add considerably to the comforts of the lower classes. Besides, there are some situations, as steep sheltered banks of good soil, which cannot be so profitably employed in any other branch of husbandry. The subject of orchards may be considered in regard to soil and situation, sorts of trees, planting, culture, and the manufacture or disposal of the produce.

#### *SECT. I. Soils and Situations most suitable for Orchards.*

4080. *The sites of all the best apple orchards*, and all the chief cider districts, have been discovered by W. Smith to be on the same stratum of red marl which stretches across the island from Dorsetshire to Yorkshire. Fruit of no kind, indeed, can be raised with much success on a soil that does not contain in its composition a portion of calcareous matter though apple trees will thrive well on any description of clay which has a dry bottom, and pears and plums on any dry-bottomed soil whatever.

4081. *The most desirable aspect* is unquestionably a somewhat elevated and naturally sheltered declivity, open to the south and south-east; but, as the author of *The Herefordshire Survey* remarks, orchards are now found "in every aspect, and on soil of every quality, and under every culture." The most approved site, he says, is that which is open to the south-east, and sheltered in other points, but particularly in that opposite.

## SECT. H. SORTS OF TREES, AND MANNER OF PLANTING. 305

Much however depends on the character of the winds of a country; for in some parts of the island, the west, and in others the east or north wind, is the most injurious to vegetation.

4082. *The soil which in Herefordshire is considered best adapted to most kinds of apples is a deep and rich loam when under the culture of the plough; on this, the trees grow with the greatest luxuriance, and produce the richest fruit. Some trees however, the sire and the golden pippin in particular, form exceptions to this general rule, and flourish most in hot shallow soils on a lime or sandstone. The best sorts of pear-trees also prefer the rich loam, but inferior kinds will even flourish where the soil will scarcely produce barbage. An orchard is generally raised with most success and at least expence in a hop-yard, the ground under this culture being always well tilled and manured, as well as fenced against every kind of enemy.*

4083. *The soils and situations devoted to farm orchards in Scotland are steep clayey banks sheltered from the more violent and injurious winds; and in whatever part of that country such situations occur, they can scarcely be more profitably employed. Fruit trees of the apple, pear and cherry kind, especially of the hardier and tall vigorous-growing varieties, might be introduced in the hedge-rows of dry and moderately sheltered grass-lands in most parts of the British Isles. By thus rendering these fruits universal, there would be a considerable accession of enjoyment to the lower classes, and less temptation to break into gardens and orchards.*

4084. *The commercial situation most desirable for an orchard is, of course, near a market town, or near a ready conveyance to one because though the making of cider affords a profit, yet the fruit sold for culinary or table use yields a much more considerable one. In *The Gloucestershire Report* it is stated that the fruit, which would fetch 8s. 16s. unground, would only bring in cider 8s. 15s.*

### SECT. II. Sorts of Trees, and Manner of Planting

4085. *The most generally useful fruit that can be grown in farm orchards is the apple next the pear then the plum for tarts or wine and to these may be added the cherry filbert, walnut, chestnut, and elder. In the cider countries, where the climate is more certain than in some others, it is customary to plant but a few good sorts and not to mix above one or two sorts together in making cider. In the northern districts, on the contrary it is a maxim to plant a considerable number of different sorts, both of those which blossom early and late because, should the blossom of one variety be destroyed by a frosty wind, that of another may escape. In cold districts it is advisable to plant orchards in sheltered hollows, exposed to the sun, and to plant thick but in the warmer southern countries, many descriptions of cider and perry fruits may be grown to perfection in the hedge-rows, or as cultured trees in permanent pastures. The fittest trees for such purposes are those which grow tall, with upright shoots, and which bear fruit of a small size such as the Siberian pippin apple, and squash teuton pear such trees shade the hedges or pastures less than the spreading kinds, and their fruit being small, is less likely to be blown down by high winds.*

4086. *The most approved sorts of cider apples we have enumerated and partially described in the accompanying table (4089). It will be particularly observed that some of the sorts form much more handsome trees than others, and should therefore be preferred for hedge-rows, and indeed in all cases where the quality of the fruit is not objectionable. Some also have smaller-sized fruit than others, and these are to be preferred for situations exposed to much wind.*

4087. *The colours of good cider fruit are red and yellow the colour to be avoided is green, as affording a liquor of the harshest and generally of the poorest quality. The pulp should be yellow, and the taste rich and somewhat astringent. Apples of a small size are always, if equal in quality to be preferred to those of a larger, in order that the rind and kernel, which contain the aromatic part, may be the more easily crushed with the pulp.*

4088. *The sorts of baking apples most suitable for orchards are the calvilles, of which there are several varieties, including the Hawthornden for early use; the reinettes, pearmaines, and Northern greening for autumn use, and the russets and Redley's pippin for winter and spring. Many other sorts might be named, but an inspection of the fruit markets will prove that these are the best and further details belong to books on gardening. Whoever intends to plant an orchard will do well to describe the soil, situation, climate, and object in view, to the nearest resident gardener or nurseryman of science and great experience because the nomenclature of fruits is at present too uncertain to justify any one in trusting entirely to a selection of names taken from books. Ronalds of Brentford, Gibbs of Amptill and Old Brompton, and Pearson of Chilwell, near Nottingham, are very extensive growers of apple trees for sale, and have paid great attention to the merits of the different sorts.*

## 1908. TABLE OF CIDER APPLES OF ESTABLISHED REPUTATION

[illegible]

to be pastured or dug, they may be planted in quincunx and close; but where it is to be ploughed, they should either be planted in rows with sufficient space between for one broad ridge, or two ordinary ones; or they should be planted in squares to admit of ploughing both east and west, and north and south.

4107. *The Hertsfordshire orchardists* recommend that the rows should extend from north to south, as in that direction each part of every tree will receive the most equal portions of light and heat. The distance between each row, as well as the space between each tree, should depend on the situation and soil. Where the former is high and exposed, the trees should be closely planted to afford each other protection, and where the latter is poor and shallow their growth will of course be less luxuriant, and they will consequently require less room. But in low and sheltered situations, and in deep and rich soils, wider intervals should be allowed. In the former instances, twelve yards between each row, and six between each tree, are sufficient; in the latter twenty-four yards between each row and eight between each tree, will not be too much.

4108. *As a general guide with regard to distance*, Nicol states the extreme limits at which apple and pear trees should stand in a properly planted and close orchard, as from thirty to forty feet, less or more according to the quality of the soil, taking, as the medium, thirty six feet. In a poor soil and a bleak exposure, where the trees may not be expected to grow very freely thirty feet are sufficient whereas in good soil and a sheltered situation, forty may not be too much. Cherries and pines may be planted at from twenty four to thirty-six feet, according to soil and situation, as above, taking as a medium, thirty feet for the ultimate distance at which they are to stand clear of one another. But it would be advisable, in the first instance to plant four trees for one that is intended ultimately to remain planting the proper kinds at the above distances first, and then temporary plants between them each way. These temporary plants should be of the free-growing sorts that begin to bear early such as the nottingham and Hawsborden apples, the May duke cherry and the Crawford and year years or any others known to produce fruit sooner after planting. These should be considered and be treated as temporary plants from the beginning, and must give place to the principal trees as they advance in growth by being pruned away bit by bit, and at last stubbed up entirely. In bleak situations, if forest and other hardy trees be planted among the fruit trees, it may not be necessary to plant so many (if any) temporary fruit trees or these may chiefly consist of the hardier sorts, such as the Hawsborden apple, the May-duce and morella cherries, and the Scotch gorse, which produce fruit the sooner.

4109. *In the operation of planting*, great care ought to be taken not to insert the plants deeper in the soil than they were before removal. This is a very common error in every description of tree planting and in retentive soils is ruinous to the tree. Sir C. M. Barral recommends, as a useful practice, in wet soils, or where the substratum is not suited to the apple or the pear, to plant the trees on hillocks of easy ascent, as for instance one foot higher in the centre than the level of the field, and sloping gradually to that level for three or four feet every way from the centre. By this practice, the roots will naturally follow the good surface earth whereas, if they are planted in holes, the roots are apt to abut on the prejudicial subsoil, to the eventual injury of the plants by canker and other diseases. When trees are thus planted on small hillocks, the under-drains may pass between the rows with greater utility.

### SECT. III. Cultivation of Farm Orchards

4110. *The trees being carefully planted, watered, and tied to tall strong stakes*, require little more than common attention for several years. Every autumn or spring they should be looked over and all cross irregular shoots made during the preceding summer cut out, suckers (if any) removed from their roots, and side growths cleared from their stems.

4111. *The object in pruning young trees*, Nicol observes, is to form a proper head. Generally speaking, the shoots may be pruned in proportion to their lengths, cutting clean away such as cross one another and fanning the tree out towards the extremities on all sides thereby keeping it equally poised, and fit to resist the effects of high winds. When it is wished to throw a young tree into a bearing state, which should not be thought of, however sooner than the third or fourth year after planting, the leading branches should be very little shortened, and the lower or side branches not at all, nor should the knife be used, unless to cut out such shoots as cross one another.

4112. *After an orchard-tree is come into bearing*, Abercrombie says, continue at the time of winter pruning either every year, or every two, three, or four years, as an occasion is perceived, to cut out unproductive wood, crowded spray, and decayed parts. Also reduce long and outrunning ramblers and low stragglers, cutting them to some good lateral that grows within its limits. Where fruit-spurs are too numerous, then cut the strongest and most unsightly. Also keep the tree pretty open in the middle. If it be necessary to take off large branches from aged trees, use a chisel or saw, and afterwards smooth the wound with a sharp knife. In case old wood is to be cut down to young shoots springing below, to make the separation in summer will be of more advantage to these young shoots, though it is not a common practice, on account of the habit of many stone-fruit bearers to exude gum, when a large branch is lopped in the growing season. Observe to keep the stem clear from all lateral shoots, and eradicate all suckers from the root.

4113. *On aged trees that have run into a confusion of shoots and branches, and whose spurs have become chattered and crowded*, the saw and the knife may be exercised with freedom, observing to cut clean away all useless spray, rotten stumps, and the like useless encumbrances. Thin out the spurs moderately to let the air circulate freely among the

leaves and fruit in the summer season, and to admit the rays of the sun, so as to give the fruit colour and flavour.

4114. *In pruning the apple tree and all other standard trees*, Knight observes, the points of the external branches should be every where rendered thin and pervious to the light, so that the internal parts of the tree may not be wholly shaded by the external parts: the light should penetrate deeply into the tree on every side; but not any where through it. When the pruner has judiciously executed his work, every part of the tree, internal as well as external, will be productive of fruit, and the internal part, in unfavourable seasons, will rather receive protection than injury from the external. A tree thus pruned will not only produce much more fruit, but will also be able to support a much heavier load of it, without danger of being broken: for any given weight will depress the branch, not simply in proportion to its quantity, but in the compound proportion of its quantity and of its horizontal distance from the point of suspension, by a mode of action similar to that of the weight on the beam of the steel-yard: and hence a hundred and fifty pounds, suspended at one foot in distance from the trunk, will depress the branch which supports it no more than ten pounds, at fifteen feet in distance, would do. Every tree will, therefore, support a larger weight of fruit without danger of being broken, in proportion as the parts of such weight are made to approach nearer to its centre.

4115. *Where a tree is stunted, or the head ill-shaped*, from being originally badly pruned or barren, from having overborne itself, or from constitutional weakness, the most expeditious remedy is to head down the plant to within three, four, or five eyes (or laches, if an old tree), of the top of the stem, in order to furnish it with a new head. The recovery of a languishing tree, if not too old, will be further promoted by taking it up at the same time, and pruning the roots: for as, on the one hand, the depriving too luxuriant a tree of part even of its sound healthy roots will moderate its vigour, so, on the other to relieve a stunted or sickly tree of cankered or decayed roots, to prune the extremities of sound roots, and especially to shorten the dangling tap-roots of a plant affected by a bad subsoil, are, in connection with heading down, or very short pruning, the renovation of the soil, and draining, the most availing remedies that can be tried.

4116. *A tree often becomes stunted from an accumulation of moss*, which affects the functions of the bark, and renders the tree unfruitful. This evil is to be removed by scraping the stems and branches of an old tree: and on a young tree a hard brush will effect the purpose. Wherever the bark is decayed or cracked, Abercrombie and Forsyth direct its removal. Lyon, of Edinburgh, has lately carried this practice to so great a length as even to recommend the removal of part of the bark of young trees. Practical men, in general, however, confine the operation to cracked bark, which nature seems to attempt throwing off: and the effect in rendering the tree more fruitful and luxuriant is acknowledged by Nail in his *Account of Scottish Gardening and Orchards*, and by different writers in *The London and Calcutta Horticultural Transactions*.

4117. *The other diseases to which orchard trees are subject* are chiefly the canker gum, mildew and blight, which, as we have already observed, are rather to be prevented by such culture as will induce a healthy state, than to be remedied by topical applications. Too much lime, Mr H. Davy thinks, may bring on the canker, and if so, the replacing a part of such soil with alluvial or vegetable earth would be of service. The gum, it is said, may be constitutional, arising from offensive matter in the soil: or local, arising from external injury. In the former case, improve the soil; in the latter, apply the knife. The mildew, it is observed by T. A. Knight and Abercrombie, "may be easily subdued at its appearance, by scattering flour of sulphur upon the infected parts." As this disease is now generally considered the growth of parasitical fungi, the above remedy is likely to succeed. For caterpillars and other insects in spring, Forsyth recommends burning rotten wood, weeds, potato-hum, wet straw, &c., on the windward side of the trees when they are in blossom. He also recommends washing the stems and branches of all orchard trees with a mixture of "fresh cow-dung with urine and soap-suds, as a whitewasher would wash the ceiling or walls of a room." The promised advantages are, destruction of insects and "fine bark;" more especially, he adds, "when you see it necessary to take all the outer bark off."

4118. *With the Hertsfordshire orchardists pruning is not in general use*; the most approved method is that of rendering thin and pervious to the light the points of the external branches, so that the internal branches of the tree may not be wholly shaded by the external parts. Large branches should rarely or never be amputated. The instrument generally used for the purpose of pruning is a strong flat chisel, fixed to a handle six feet or more in length, having a sharp edge on one of its sides and a hook on the other. (Knight's *Treatise on the Apple and Pear*.)

4119. *The culture of the soil among orchard trees* is always attended with advantage; though it can so seldom be properly conducted in farm orchards, that in most cases it is better to lay them down with grass seeds for pasture. To plough between the trees and take corn crops, even if manure is regularly given, cannot be any great advantage, unless

a radius of six or eight feet is left round each tree. If such a space is left, and yearly dug but not cropped, the trees will thrive well; and a ridge between each two rows may be sown with corn. The greater number of orchards in Herefordshire and Gloucestershire are under pasture; but the most productive are those trees grown in hop grounds. In Kent, in some instances, the interspaces of young orchards are occupied by hops, in others by alberts, and in grown orchards the latter are sometimes seen. Some old orchards are likewise in permanent sward, others under arable or garden crops, and some in meadow, while others are in lucern. In all cases where the subsoil is moist, or otherwise unfavourable, the ground of an orchard should neither be dug nor ploughed, in order not to prevent the roots from spreading themselves immediately under the surface. The effect of repeatedly stirring the surface to six or eight inches or more in depth is to cause the roots to descend. In all soils, this descent, by furnishing them more abundantly with moisture, tends to prolong the growth, and prevent the ripening of the wood and the formation of blossom buds; but, in the case of nervous subsoils, it brings on canker and other diseases. This is the reason why standard fruit-trees in kitchen gardens are generally less productive than in grass orchards: the productive trees in certain hop-grounds in Kent and other counties may seem an exception; but they are not so, the subsoil in these cases being good and dry.

#### SECT. IV. *Gathering and Keeping of Orchard Fruit.*

4190. The gathering of orchard fruit, and especially apples, should be performed in such a manner as not to damage the branches, or break off the fruit spurs or buds. Too frequently the fruit is allowed to drop, or it is beat and bruised by shaking the tree and using long poles, &c. Nicol directs that it should never be allowed to drop of itself, nor should it be shaken down, but should be pulled by the hand. This may be thought too troublesome a method, but every body knows that bruised fruit will not keep, nor will it bring a full price. The expense of gathering, therefore, may be more than defrayed, if carefully done by saving the fruit from blemish.

4121. With regard to the keeping of kernel fruits, the old practice, which is recommended by Marshall and Forsyth, commences with sweating, though Nicol and other modern gardeners omit this process. It is evident from the general practice of both commercial and private gardeners, that sweating fruit is not essential to its keeping, though some persons continue to allege that, in consequence of that operation, it keeps better. Marshall, the author of *An Introduction to Gardening* observes, that those fruits which continue long for use should be suffered to hang late, even to November, if the frost will permit; for they must be well ripened or they will shrink. Lay them in heaps till they have sweated a few days, when they must be wiped dry. Let them then lie singly or at least thinly, for about a fortnight, and be again wiped, and immediately packed in boxes and hampers, lined with double or treble sheets of paper. Place them gently in, and cover them close, so as to keep air out as much as possible. Preserve them from frost through the winter: never use hay for the purpose. Kernel fruits and nuts keep no where better than when mixed and covered with sand in a dry cool cellar in the manner of potatoes. Buried in pits well protected from moisture, russets have been found to keep perfectly fresh a year from the time of their being gathered. The keeping of cider fruits is not approved of, it being found best to crush them after they have been thinly spread for a few days on a dry boarded floor. Many of the Herefordshire growers carry them direct from the tree to the crushing-mill.

#### SECT. V. *Manufacture of Cider and Perry.*

4122. Cider is commonly manufactured by the grower of the fruit, though it would certainly be better for the public if it were made a distinct branch of business like brewing or distilling. "The true way to have excellent cider," Marshall observes, "is to dispose of the fruit to professional cider makers. The principal part of the prime cider sold in London and elsewhere is manufactured by professional men; by men who make a business of manufacturing and rectifying cider, even as distillers, rectifiers of spirit, and brewers follow their businesses or professions, and like them too conduct their operations, more or less, on scientific principles." (*Rev. of Agr. Rep.* vol. ii. p. 394.) It is allowed on all hands that the operation is performed in a most slovenly manner by the farmer and that it is very difficult to procure this liquor in good quality. The operation of cider-making is as simple as that of wine-making or brewing, and will be perfectly understood from the following directions, chiefly drawn from the treatise of Crocker and Knight; so that any person possessing an orchard, or a few hedge-row fruit trees, may make a supply for his own use. The first business consists of gathering and preparing the fruit; the second, of grinding and pressing; and the last, of fermenting and bottling.

4123. In gathering cider apples, care should be taken that they are thoroughly ripe before they are taken from the tree; otherwise the cider will be of a rough, harsh taste, in spite of all the endeavours of the operator. It is observed by Crocker, in his treatise

on *The Art of Making and Managing Cider*, that the most certain indications of the ripeness of apples are the fragrance of their smell, and their spontaneously dropping from the trees. When they are in this state of maturity, in a dry day, the limbs may, he says, be slightly shaken, and partly disburdened of their golden store, thus taking such apples only as are ripe, and leaving the unripe longer on the trees, that they may also require a due degree of maturity. It may not, he thinks, be amiss to make three gatherings of the crop, hanging each by itself. The latter gathering, as well as wind-falls, can, however, only be employed in making inferior cider: the prime cider must be drawn from the former gatherings.

4124. *On the proper mixture of fruits*, or rather on their proper separation, the merit of cider will always greatly depend. Those whose rinds and pulp are tinged with green, or red without any mixture of yellow, as that colour will disappear in the first stages of fermentation, should be carefully kept apart from such as are yellow, or yellow intermixed with red. The latter kinds, which should remain on the trees till ripe enough to fall without being much shaken, are alone capable of making fine cider. Each kind should be collected separately as noticed above, and kept till it becomes perfectly mellow. For this purpose, in the common practice of the country they are placed in heaps of ten inches or a foot thick, and exposed to the sun, air, and rain, not being ever covered, except in very severe frosts. The strength and flavour of the future liquor are increased by keeping the fruit under cover some time before it is ground, but unless a situation can be afforded it, in which it is exposed to a free current of air, and where it can be spread very thin, it is apt to contract an unpleasant smell, which will much affect the cider produced from it. Few farms are provided with proper buildings for this purpose on a large scale, and the improvement of the liquor will not nearly pay the expense of erecting them. It may reasonably be supposed, that much water is absorbed by the fruit in a rainy season: but the quantity of juice yielded by any given quantity of fruit will be found to diminish as it becomes more mellow, even in very wet weather provided it be ground when thoroughly dry. The advantages therefore, of covering the fruit will probably be much less than may at first sight be expected. No criterion appears to be known, by which the most proper point of maturity in the fruit can be ascertained with accuracy: but it improves as long as it continues to acquire a deeper shade of yellow. Each heap should be examined prior to its being ground, and any decayed or green fruit carefully taken away. The expense of this will be very small, and will be amply repaid by the excellence of the liquor: and the ease with which too great a degree of fermentation may be prevented. (Crocker.) In Ireland a mixture of every sort of apple is considered as producing the best cider. A proportion of crab is always admitted. "The taste, in consequence, is very sour, and less sweet than English cider: but this is matter of fancy: and, a relish for rough cider once acquired, the sweet kind loses much of its attractions. Owing to a considerable admixture of crab, the Irish cider is always more sour than the English, and this is a quality when not too predominant, for which it is valued by the natives." (Lardner's *Cyclo. Dom. Econ.*)

4125. *In grinding*, the fruit should be so reduced that the rind and kernel should be scarcely discernible. In such a complete mixture it seems probable that new elective attractions will be exerted, and compounds formed which did not exist previously to the fruit being placed under the roller. The process of slow grinding, with free access of air gives the cider good qualities it did not possess before, probably by the absorption of oxygen. To procure very fine cider, the fruit should be ground and pressed imperfectly and the pulp spread as thin as possible, exposed to the air, and frequently turned during twenty-four hours, to obtain as large an absorption of air as possible. The pulp should be ground again, and the liquor formerly expressed added, by which the liquor will acquire an increase of strength and richness. (Lardner's *Cyclo. Dom. Econ.*)

4126. *Whether the pomace should, immediately after grinding, be conveyed to the press*, there to be formed into a kind of cake, or what is called the cheese; or whether it should remain some time in that state before pressing, ciderists have not agreed. Some say it should be pressed immediately after grinding; others conceive it best to suffer it to remain in the grinding trough, or in vats employed for the purpose, for twenty-four hours, or even two days, that it may acquire not only a redness of colour, but also that it may form an extract with the rind and kernel. Both extremes are, Crocker thinks, wrong. There is an analogy, he says, between the making of cider from apples, and wine from grapes; and the method which the wine-maker pursues ought to be followed by the cider-maker. When the pulp of the grapes has lain some time in the vats, the vintager thrusts his hand into the pulp, and takes some from the middle of the mass and when he perceives, by the smell, that the rancid sweetness is gone off, and that his nose is affected with a slight piquancy, he immediately carries it to the press, and by a light pressure expresses his prime juice. In like manner should the ciderist determine

the time when his pulp should be carried to the press. If he carried it immediately from the mill to the press, he might lose some small advantage which may be expected from the mud and kernels, and his liquor might be of lower colour than he may wish. If he suffer it to remain too long unpressed, he will find to his cost that the acetous fermentation will come on before the vinous is perfected, especially in the early part of the cider-making season. He will generally find that his pulp is in a fit state for pressing in about twelve or sixteen hours. If he must of necessity keep it in that state longer he will find a sensible heat therein, which will engender a premature fermentation and he must not delay turning it over, thereby to expose the middle of the mass to the influence of the atmosphere. Knight's opinion is, however, that it should remain twenty-four hours before it is taken to the press; and in this opinion the author of the Art of Cider Making, in *Lardner's Cyclopædia, Domestic Economy*, vol. 1. also concurs.

4127 *The pommage being carried to the press, and a square cake or cheese made of it, by placing very clean sweet straw or reed between the various layers of pommage; or by putting the same into the hair-cloths, and placing them one on another. It is of importance that the straw or reed be sweet, and perfectly free from any mustiness, lest the cider be impregnated therewith. Particular care ought also to be taken to keep hair-cloths sweet, by frequently washing and drying, or the ill effects of their acidity will be communicated to the cider. To this cake or cheese, after standing awhile, a slight pressure is at first to be given, which must be gradually increased until all the must or juice is expressed after which, this juice must be strained through a coarse hair sieve, to keep back its gross feculences, and be put into proper vessels. These vessels may be either open vats or close casks; but as, in the time of a plentiful crop of apples, a number of open vats may by the ciderist be considered an incumbrance in his cider-room, they should be generally carried immediately from the press to the cask. Thus far, says Crocker cider-making is a mere manual operation, performed with very little skill in the operator but here it is that the great art of making good cider commences; nature soon begins to work a wonderful change in this foul-looking, turbid, fulsome, and unwholesome fluid and, by the process of fermentation alone, converts it into a wholesome, vinous, salubrious, heart-cheering beverage.*

4128. *Fermentation is an internal motion of the parts of a fermentable body. This motion, in the present case is always accompanied with an evident ebullition, the bubbles rising to the surface, and there forming a scum, or soft and spongy crust, over the whole liquor. This crust is frequently raised and broken by the air as it disengages itself from the liquor, and forces its way through it. This effect continues whilst the fermentation is brisk, but at last gradually ceases. The liquor now appears tolerably clear to the eye, and has a piquant vinous sharpness upon the tongue. If in this state the least hissing noise be heard in the fermenting liquor, the room is too warm, and atmospheric air must be let in at the doors and at the windows. Now continues Crocker, is the critical moment which the ciderist must not lose sight of for, if he would have a strong, generous, and pleasant liquor all further sensible fermentation must be stopped. This is best done by racking off the pure part into open vessels, which must be placed in a more cool situation for a day or two after which it may again be bottled, and placed in some moderately cool situation for the winter. The Herefordshire cider-farmers, after the cider has perfected its vinous fermentation, place their casks of cider in open sheds throughout the winter, and, when the spring advances, give the last racking, and then cellar it. In racking, it is advisable that the stream from the racking-cock be small, and that the receiving tub be but a small depth below the cock, lest, by exciting a violent motion of the parts of the liquor another fermentation be brought up. The feculences of the cider may be strained through a filtering bag, and placed among the second-rate ciders; but by no means should it be returned to the prime cider. In this situation the cider will in course of time, by a sort of insensible fermentation, not only drop the remainder of its gross lees, but will become transparent, highly vinous, and fragrant.*

4129 *According to Knight, after the fermentation has ceased, and the liquor is become clear and bright, it should instantly be drawn off, and not suffered on any account again to mingle with its lees for these possess much the same properties as yeast, and would inevitably bring on a second fermentation. The best criterion to judge of the proper moment to rack off will be the brightness of the liquor and this is always attended with external marks, which serve as guides to the cider-maker. The discharge of fixed air, which always attends the progress of fermentation, has entirely ceased and a thick crust, formed of fragments of the reduced pulp, raised by the buoyant air it contains, is collected on the surface. The clear liquor being drawn off into another cask, the lees are put into small bags, similar to those used for jellies; through these whatever liquor the lees contain gradually filtrates, becoming perfectly bright, and it is then returned to that in the cask, in which it has the effect, in some measure, of preventing a second fermentation. It appears to have undergone a considerable change in the process of filtration,*

Its colour is remarkably deep, its taste harsh and flat, and it has a strong tendency to become acetous, probably by having given out fixed and absorbed vital air. Should it become acetous, which it will frequently do in forty-eight hours, it must not on any account be put into the cask. If the cider, after being racked off, remains bright and quiet, nothing more is to be done to it till the succeeding spring; but if a scum collects on the surface, it must immediately be racked off into another cask, as this would produce bad effects if suffered to sink. If a disposition to ferment with violence again appears, it will be necessary to rack off from one cask to another, as often as a hazing noise is heard. The strength of cider is much reduced by being frequently racked off but this arises only from a larger portion of sugar remaining unchanged, which adds to the sweetness at the expense of the other quality. The juice of those fruits which produce very strong ciders often remains moddy during the whole winter, and much attention must frequently be paid to prevent an excess of fermentation.

4130. The casks, into which the liquor is put whenever racked off, should always have been thoroughly scalded, and dried again, and each should want several gallons of being full, to expose a larger surface to the air.

4131. The above precautions neglected by the ciderist, the inevitable consequence will be this. — Another fermentation will quickly succeed, and convert the fine vinous liquor he was possessed of into a sort of vinegar, and all the art he is master of will never restore it to its former richness and purity. When the acetous fermentation has been suffered to come on, the following attempts may be made to prevent the ill effects of it from running to their full extent. — A bottle of French brandy, half a gallon of spirit extracted from the lees of cider or a pailful of old cider poured into the hogshead soon after the acetous fermentation is begun but no wonder if all these should fail if the cider be still continued in a close warm cellar. To give effect to either, it is necessary that the liquor be as much exposed to a cooler air as conveniently may be, and that for a considerable length of time. By such means it is possible fermentation may, in a great measure, be repressed and if a cask of prime cider cannot thence be obtained, a cask of tolerable second-rate kind may. These remedies are innocent but if the farmer or cider-merchant attempts to cover the accident, occasioned by negligence or inattention, by applying any preparation of lead, let him reflect, that he is about to commit an absolute and unqualified murder on those whose lot it may be to drink his poisonous draught.

4132. *Stumping*, which signifies the fuming of a cask with burning sulphur, may sometimes be advantageous. It is thus performed. — Take a stripe of canvas cloth, about twelve inches long and two broad let it be dipped into melted brimstone when the match is dry, let it be lighted, and suspended from the bung of a cask (in which there are a few gallons of cider) until it be burnt out. The cask must remain stopped for an hour or more, and be then rolled to and fro, to incorporate the fumes of the match with the cider after which it may be filled. If the stumping be designed only to suppress some slight improper fermentation, the brimstone match is sufficient but if it be required to give any additional flavour to the cider some powdered ginger, cloves, cinnamon, &c. may be strewed on the match when it is made. The burning of these ingredients with the sulphur will convey somewhat of their fragrance to the whole cask of cider but to do it to the best advantage, it must be performed as soon as the vinous fermentation is fully perfected.

4133. *Cider is generally in the best state to be put into the bottle at two years old, where it will soon become brisk and sparkling and if it possesses much richness, it will remain with scarcely any sensible change during twenty or thirty years, or as long as the cork duly performs its office.*

4134. *In making cider for the common use of the farm-house, few of the foregoing rules are attended to. The flavour of the liquor is here a secondary consideration with the farmer, whose first object must be to obtain a large quantity at a small expense. The apples are usually ground as soon as they become moderately ripe and the juice is either soaked off at once as soon as it becomes bright, or more frequently conveyed from the press immediately to the cask. A violent fermentation soon commences, and continues until nearly the whole of the saccharine part is decomposed. The casks are filled up and stopped early in the succeeding spring, and no further attention is either paid or required. The liquor thus prepared may be kept from two to five or six years in the cask, according to its strength. It is generally harsh and rough, but rarely acetous; and in this state, it is usually supposed to be preferred by the farmers and peasantry. When it has become extremely thin and harsh by excess of fermentation, the addition of a small quantity of bruised wheat, or slices of toasted bread, or any other firmaceous substance, will much diminish its disposition to become sour.*

6135. *Mustard Cider.* Take new cider from the press, mix it with honey till it bears an egg, beat it gently for a quarter of an hour, put out in an hour and take off the scum as it rises, let it cool, then pour it, without straining the vessel quite full, bottle it off in March. In six weeks afterwards, it will be ripe for use, and as strong as Mustard. The longer it is afterwards kept, the better. (Month. Mag.)

4186. *Perry* is manufactured on exactly the same principles as *cider*. The pears should not be quite ripe, and the admixture of some wildings will add much to the sprightliness of the taste. "It is thought by some to resemble champagne more than gooseberry wine does; and it is said, when of the best quality, to have been at times sold instead of champagne." (*Lardner's Cyc. Dom. Econ.*)

4187. The produce of *cider* or *perry* by the acre can only be guessed at, by first ascertaining the number of trees. From an orchard of trees in full bearing, half a hogshead of *cider* may, in seasons ordinarily favourable, be expected from the fruit of each tree. As the number of trees on the acre varies from ten to forty the quantity of *cider* must vary in the same proportion, that is, from five to twenty hogsheads. Pear-trees, in equally good bearing, yield fully one third more liquor; therefore, although the liquor extracted from pears sells at a lower price than that produced from apples, yet the value by the acre, when the number of trees is the same, is nearly on a par.

#### SECT. VI. Machinery and Utensils necessary for Cider-making.

4188. The machinery of the common *ciderist* includes the mill-house, mill, press, cloth, vat, and cask, with their appurtenances.

4189. Marshall, in *The Rural Economy of Gloucestershire*, remarks, that a mill-house, on an orchard-farm, is as necessary as a barn. It is generally one end of an out-building, or perhaps an open shed, under which straw or small implements are occasionally laid up. The smallest dimensions, to render it any way convenient, are twenty-four feet by twenty a floor thrown over it, at seven feet high a door in the middle of the front, and a window opposite with the mill on one side, the press on the other side, of the window, as much room being left in front, towards the door, for fruit and utensils, as the nature of the mill and the press will allow. The utensils belonging to a mill-house are few the fruit is brought in carts or baskets, and the liquor carried out in pails.

4190. Of the common *cider-mill* there are several varieties, formed on the principles of the hand-mills of tanners. The circle enclosed by the trough is in Devonshire generally in one division (*fig. 602.*) and

is sometimes divided into compartments for containing different varieties of the same fruit (*fig. 603.*) The size of the runner varies from two and a half to four and a half feet in diameter and from nine to twelve inches in thickness which in general is equal, like that of a grindstone, not varying like that of a millstone the weight one or two tons. The bottom of the chace is somewhat wider than the runner that this may run freely. The inner side rises perpendicularly but the outer side spreads, so as to make the top of the trough some six or eight inches wider than the bottom to give freedom to the runner and room to scatter in the fruit, stir it up while grinding, and take out the ground matter. The depth is nine or ten inches. The outer rim of the trough is three or four inches wide; and the diameter of the inner circle, which the trough circumscribes from four and a half to five feet, according to the size of the mill. This is sometimes raised by a table of thick plank fixed upon the stone, with a curb of wood, lessening to an angle, fixed upon the circumference of the trough, making the whole depth of the trough about equal to its width at the bottom. This lessens the quantity of the stone and the plank upon the centre answers other purposes. The entire bed of a middle-sized mill is about nine feet some are ten and some few twelve, in diameter the whole being composed of two, three, or four stones, cramped together as one, and worked, or at least finished, after they are cramped together. The best stones are raised in the Forest of Dean they are mostly a dark-reddish gritstone (non-calcareous), working with sufficient freedom, yet sufficiently hard for this intention. The bed of the mill is formed, and the trough partly hollowed, at the quarry, leaving a few inches at the edge of each stone uncut out, as a bond to prevent its breaking in carriage. Much depends on the quality of the stone. It ought not to be calcareous, in whole or in part, as the acid of the liquor would corrode it. Some of the Herefordshire stones have calcareous pebbles in them, which being of course dissolved leave holes in the stone. Nor should it be such as will communicate a disagreeable tinge to the liquor. A clean-grained gritstone grit is the fittest for the purpose.

4191. The runner as it has been seen (*fig. 602.*) is moved by means of an axle passing through the centre, with a long arm, reaching without the head of the mill, for a horse to draw by and with a short one passing to an upright swivel, turning upon a pivot, in the centre of the stone, and studded at the top, by entering a bearing of the floor above. An arm bolt, with a large head, passes through an eye in the lower part of the wheel, into the end of the inner arm of the axle. Thus the requisite double motion is obtained, and the stone kept perfectly upright (which it ought to be) with great simplicity, and without stress to any part of the machine. This is the ordinary method of hanging the runner. There is a more complex way of doing it, but Marshall says he sees no advantage arising from it. There are some mills, it seems, with two runners, one opposite the other. On the lower arm of the axle, about a foot from the

runner, is fixed (or ought to be, though it is frequently wanting) a cogged wheel working in a circle of cogs, fixed upon the bed of the mill.

4142. The diameter of the wheel is determined by the height of the axle above the bed of the mill. The diameter of the ring of cogs, by the distance of the wheel from the centre of motion. The use of cog wheels is to prevent the runner from sliding, to which it is liable when the mill is full; the water, when nearly ground, rising up in a body before the stone. Besides, by causing the rotatory motion of the stone, it renders the work more easy to the horse. These wheels require to be made with great exactness and in a country where cogs are uncommon to France, a millwright should be employed in fixing them. The mill is placed so as to leave a horse-path, about three feet wide, between the bed and the walls; so that a moderately sized mill, with its horse-path, takes up a space of fourteen or fifteen feet every way.

4143. A cider-mill in use in the south of France (Fig. 804.) is worked on a circular platform of boards,

and instead of stone the wheel or cast-iron roller (a) is of cast-iron. The fruit is spread thinly over the platform, and the roller moved round by one man or a woman. From the roller's covering more breadth than the narrow bark wheels in use in England more fruit is crushed in a short time by this sort of mill than would at first sight be supposed.

4144. An elegant description of mills, where cider is only made for private use, consists of a pair of stired rollers working into each other. These rollers are of cast-iron, hollow, about nine inches in diameter with staves or teeth about an inch wide, and nearly as much deep. In general they are worked by hand, two men working against each other. Between them the fruit passes twice the rollers being first set wide to break it into fragments, and afterwards closer to reduce

the fragments and the seeds, the bruising of the latter being of essential use in making high-flavoured cider.

4145. The cider-out is an iron machine. Where iron-mills have been tried, this metal has been found to be soluble in the acid of apples, to which it communicates a brown colour and an unpleasant taste. No combination has been ascertained to take place between this acid and lead but as the calx of this metal readily dissolves in, and communicates an extremely poisonous quality to, the sweetest juice of the apple, it should never be suffered to come into contact with the fruit or liquor. (*Keight on the Apple and Pear*). In Ireland the cider-mill is composed of two horizontal wooden cylinders, covered with staves of iron like an open barrel. These work into each other and crush the apples, which are afterwards beat in a vessel with wooden poles.

4146. The cider-press in Herefordshire is a modification of the common screw press. In Ireland the press bears a considerable resemblance to the common wine-presses of France that being effected by a long lever which in England is effected by a screw. It will save some subsequent trouble if, in pressing out the juice, the action of the press be applied gradually, and very slowly increased. In this way the juice, at first running thickly will at length come off perfectly transparent. (*Londres & Spain, Dom. Rom.*)

4147. Cider cloths are used for containing the pommage in order to its being pressed. They are usually made of common hair-cloth; but such as is rather close in its texture is the best. The size is generally about four feet square and they hold about two or three bushels, or as much as the mill can grind at once and these are heaped over each other till the press is full. The larger presses will hold from eight to fifteen bags, which yield from one to two hundred gallons of liquor, according to the largeness of what is termed the cheese. To perform the work neatly, it is necessary to have two sets of these bags: for they clog and fur in pressing, and consequently become unfit for use till they have been washed and dried, so that, while this is doing either the press must stand still or another set be ready to employ it. But some, instead of hair bags, lay long straw under the pommage, the ends of which they turn up over it then cover the pommage entirely with fresh clean straw, upon which they spread another layer of pommage, and so on alternately, till the press is full. Either of the methods will do but those who are desirous of doing the work in the neatest and best manner generally use bags.

4148. The cider-out is a vessel made for the purpose of receiving the pommage, or the cider before it is racked off into the cask. Vessels of this kind should be made of wood, as where lead is employed it is liable to be corroded by the malic acid.

4149. Cider casks, when new, though the wood be ever so well seasoned, are apt to give a disagreeable rotch, unless due caution be used before-hand. Frequent scalding with hot water, into which some handfuls of salt have been first thrown, or with water in which some of the pommage has been boiled, and washing afterwards with cider, are the usual remedies against this evil, and seldom fail of removing it effectually. Of old casks, beer-vessels are the worst, as they always spoil cider and, in return, cider-casks infallibly spoil beer. Wine and brandy casks do very well, provided the tartar adhering to their sides be carefully scraped off, and they are well acidified.

## CHAP. XI.

### Laying out of Farms and other Culturable Lands.

4150. The farming lands of an estate are in general the great source of its annual rental. The domestic lands are chiefly for enjoyment the roads afford no direct income the villages, manufactories, commonly the mines and fisheries, and often also

the woods, yield no income of consequence; but there remain the lands to be let out to the professional farmer, market-gardener, nurseryman, and cottagers from these the landlord generally derives his principal return for the capital laid out on the estate. Having therefore disposed of all the other parts of the territory, it remains only to arrange the farming or culturable lands in farms of different characters and uses, in cottage lands, gardens, or orchard grounds these may be considered in regard to their extent and arrangement.

#### SECT. I. *Extent or Size of Farm and Cottage Lands.*

4151. *The proper use of farms*, or of land to be let in any way, must necessarily be that which best suits the markets not altogether the market of the moment, for there may be a run for large or for small farms; but the market on an average of years, times, and circumstances.

4152. *The enlargement or diminution of farms* can proceed only for a time, and to a limited extent. The interest of the landlord, which gave the first impulse, is ever vigilant to check its progress, when it is attempted to carry the measure beyond due bounds. It is in this that the security of the public consists, if it were ever possible that the public interest should be endangered by the enlargement of farms. Accordingly, in most of our counties, a few tenants, of superior knowledge and capital have been seen to hold considerable tracts of land, which, after a few years, were divided into a number of separate farms. The practice of these men is a lesson to their neighbours and their success never fails to bring forward, at the expiration of their leases, a number of competitors. Whenever skill and capital come to be generally diffused, there can be few instances of very large farms, if a fair competition be permitted. No individual, whatever may be his fortune and abilities, can then pay so high a rent for several farms, each of them of such a size as to give full room for the use of machinery, and other economical arrangements, as can be got from separate tenants. The impossibility of exercising that vigilant superintendence, which is so indispensable in agricultural concerns, cannot long be compensated by any advantages which a great farmer may possess. His operations cannot be brought together to one spot, like those of the manufacturer, the materials on which he works are seldom in the same state for a few days, and his instruments, animated and mechanical, are exposed to a great many accidents, which his judgment and experience must be called forth instantly to repair.

4153. *If we examine the various uses of farms in those districts where the most perfect freedom exists*, and the best management prevails, we shall find them determined, with few exceptions, by the degree of superintendence which they require. Hence, pastoral farms are the largest next, such as are composed both of grazing and tillage lands then such rich soils as carry cultivated crops every year, and, finally, the farms near large towns, where the grower of corn gradually gives way to the market gardener cultivating his little spot by manual labour. The hills of the south of Scotland are distributed into farms of the first class the counties of Berwick and Roxburgh into those of the second and the smaller farms of the Lothians and of the Carse of Gowrie, where there seems to be no want of capital for the management of large farms, are a sufficient proof of the general principle which determines the size of farms. (*Sup. Encyc. Brit. art. Agr.*)

#### SECT. II. *Laying out Farms and Farmhouses.*

4154. *The arrangement of farms* naturally divides itself into whatever relates to the farmery or home-stall, and what relates to the arrangement of the fields, roads, fences, and water-courses. In a country like Britain, long under cultivation, it is but seldom that these can be brought completely under the control of the improver but cases occur where this may be done without restraint, as in the enclosure of large commons; and in Ireland and the highlands of Scotland the opportunities are frequent.

##### SUBSECT. I. *Situation and Arrangement of the Farmery.*

4155. *The general principles of designing farmeries and cottages* having been already treated of, we have in this place chiefly to apply them to particular cases. Though the majority of farms may be described as of mixed culture yet there are a number which are almost exclusively devoted to pasture, as mountain farms; to meadow culture, as irrigated or overflown lands, lands in particular situations, as in fenny districts, and those situated on the borders of some description of river there are others in which peculiar crops are chiefly raised, as in the case of the hop and seed farms of Kent, Essex, and Surrey. All these require a somewhat different kind and extent of accommodation in the farm buildings.

4156. *The requisites for a farmery common to most characters of farms* are, a central situation, neither too high nor too low, shelter, water, exposure to the south or south-

east, in preference to other points; a level or flat area of sufficient extent for the buildings, yards, and gardens; grass-land sufficient for one small enclosure or more; and suitable outlets to the different parts of the farm, and to public roads and markets.

4157 *Some of these requisites may be supplied by art, as wharves, by plantations; water, by wells and ponds; a flat, by levelling; and grass-lands, by culms.* the direction of the roads depends entirely on the designer. But in some cases the situation of the farmery cannot be rendered central, as it frequently happens in the fenny districts of Cambridgeshire, where danger might be incurred from extraordinary floods; and in the case of mountainous sheep farms, where a central situation might be so elevated as to be deprived of most of the other requisites. Still, even in these cases, the general requisites ought to be attained as far as practicable and there are degrees of attainment, as to a central situation, to be arrived at even among fens and mountains.

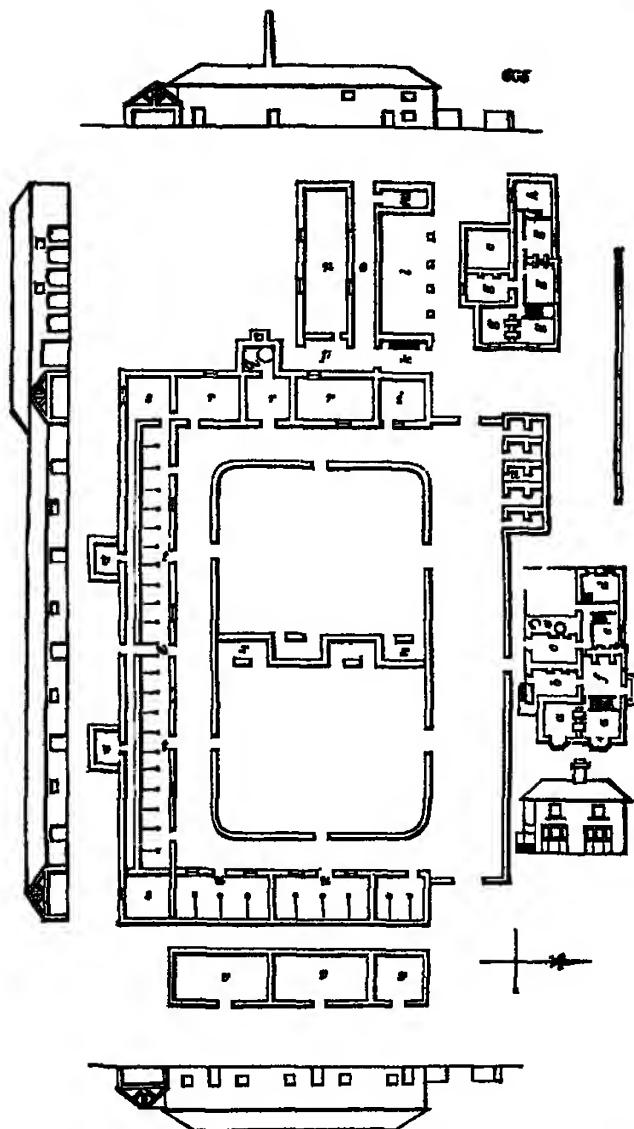

4158. *Excellent examples of different descriptions of farmeries are to be found in Berwickshire, Northumberland, East Lothian, and on the Marquis of Stafford's estates in Shropshire, Staffordshire, and Sutherland.* Besides a great number of cottages and farmeries of different descriptions, thirty-seven new farmeries have been erected by the Marquis of Stafford in Shropshire alone. Loch, Lord Stafford's agent, in describing these (*Account of Improvements on the M. of Stafford's Estates, &c.*), states, that "much attention and consideration have been given to the plans of these buildings, with the view of combining as many advantages as possible, and of arranging the different parts in such a way as to save the time of the tenant and his people, and in order that their extent might be reduced to the least size practicable, securing at the same time the accommodation required. The most approved plans in both ends of the island were consulted, and a gradual improvement has been made on them. The latter ones combine the advantages of the English and Scotch buildings, avoiding, it is hoped, their respective defects. To almost every one of these homesteads is attached a threshing machine constructed on the best principles wherever water could be obtained, that has been made use of as the impelling power and, of late, some of the more extensive farms have been provided with steam-engines for that purpose."

4159. *In selecting a few of these examples, the first we shall mention is that of Sidern, or Cider Hall in Sutherland, erected in 1818.* The soil of this farm is of a light and excellent quality, particularly suited to the Norfolk rotation of husbandry, which is followed by Ruie, the new tenant, a native of the county of Roxburgh. The house and homestead cost \$2000. It is built, in the most sufficient manner of stone and lime, and covered with Easdale slate from the west coast of Scotland. In the garden, which is an old one, there are some of the finest holly trees to be met with any where, with several apple, pear, and quince, or small black cherry trees, of so considerable a size as to show that there is nothing in the climate to prevent the growth of even the more delicate kinds of timber, if not exposed to the sea breeze.

4160. *The accommodations of the house are, on the ground floor, a parlour, lobby, and staircase, family room, pantry, and kitchen behind may be an open yard, and in front a flower-garden the chamber story a bedroom and bedchamber, two bedrooms, maid servant's room, and bedroom. The offices contain a cart-house, stable, tool-house, threshing-mill, and straw-house, horse-course, cattle-shed, dairy calf-pen, cow-byre, feeding-byre, booby (i. e. booth or lodge) for ploughmen pigsties, and poultry above, paved way, and cattle-yards.*

4161 *As an example of a Northumberland farmery for a farm of from 400 to 500 acres, we have recourse to The General Report of Scotland.* The accommodations are as follows. — In the dwelling-house are the entrance, stairs to chambers and cellars, and lobby, dining-room, pantry, coal-closet, parlour, business-room, kitchen, back-kitchen, dairy, store-room, poultry, farm-servants' kitchen, boiling-house, root-house, riding-horse stable. In the economical buildings are a cart-shed, straw-barn, and granary over corn-barns, hinds, byre for three cows, byre for ten cows, with feeding passage in the centre; calf-house, loose-horse place, stable, feeding sheds for cattle, with feeding passage along the centre pigs, dung-places, straw yards, cart-shed, and open court. The aspect of the house is south, and the garden and orchard are in front of it.

4162. *As an example of a very complete farmery for a turnip and barley soil, we give that of Fern (fig. 605.), erected by the Marquis of Stafford in the parish of Escall Magna, in Shropshire, in 1820.* The farm contains 480 acres of turnip soil, and the farmery the following accommodations, including a threshing machine driven by steam. In the house are two parlours (a, e), family-room (b), brew-house, two stories (c), pantry (d), milk-house (f), kitchen (f'), bedrooms (g), manservants bedroom (h). In the court offices a hackney-stable (i), stairs under cover (k), waggon-shed and granary over (l), tool-house (m), cow-house (n), places for turnips and straw (o, p), steam-engine (q), para (r), straw or other cattle-food (s), stall-fed cattle (t) stables (u), turnip-houses (v), biggories, poultry, tools, and necessary (w), cattle-sheds to each yard (x).

4199. As an example of a farmery to be managed by a bailiff, we give that of Skelbo, also in Sutherland. The farm consists of 450 acres, the greater part taken from a heathery waste. It contains a suitable house for the grove or bailiff, and attached to the office is a threshing machine, combining a corn or meal-mill. Its accommodations

are, a chaff-house, corn-rooms, threshing-mill, with water-wheel and straw-house; cattle-sheds, poultry-houses, and piggery; stables, byres, cart-shed, cattle-shed, dairy, meal-house, lodge for ploughman, paved way, and cattle-yards.

4164. *As an example of a small farmery in the county of Stafford, we select that of Knollwall. (Ag. 606.)* The extent is 104

acres; the soil is strong and rather wet, and there are some water and other meadows. The house and yard-buildings are of brick and tile, and their accommodations are, a kitchen (a), a brew-house (b), parlour (c), sitting-room (d), pantry (e), milk-house (f), court-yard open (g), coals (h), hackney-stable (i), turkey-house (k), pigsties (l), waggon-horse stable (m), corn-bay (n), barn (o), straw-bay (p), cow-tyings (q), fodder-bins (r), calf-houses (s), and waggon-shed, granary over, connected with barn (s).

4165. *As an example of a middle-sized farmery on a clayey soil, we may refer to that of Newstead, in Staffordshire.* This farm contains 314 acres, and the tenant, Ford, is said to be an example to the whole country. The accommodations of the farmery are, in the dwelling-house, an outer kitchen, and kitchen, master's room, brew-house, dairy pantry, parlour, bedrooms, cheese-room attic. In

the court a shed for waggons, with granary over, hackney stable, waggon-horse stable, cattle-sheds, turnip-houses, fodder-house, straw-bays, threshing-mill with water-wheel, corn-bay, tool-house, workshop, bay for unthreshed corn, small granary, and pigsties.

4166. *As an example of an economical farmery for a farm of 50 or 60 acres, we copy from The General Report of Scotland.* The accommodations are:—in the house, a kitchen, parlour, store-room, pantry, with three bedrooms, and a light closet over closet, milk-room, and scullery. In the economical buildings are, a stable with a loose stall, byre for ten cows, cattle-shed, barn, cart-shed, with granary over pigsties and cattle-yard. This appears one of the most compact and eligible plans for the farmer of arable farms under 100 acres.

4167. *As an improved Berwickshire farmery we submit another specimen from The General Report.* Its accommodations are calculated for a farm of 600 acres, and consist, in the dwelling-house range, of a porch, lobby, dining-room, parlour, kitchen, scullery, coal-place, store-room, dairy, pantry, business-room, poultry steaming-house, bailiff's room. The economical buildings contain a riding-horse stable, tool-house, cart-shed, with granary over; corn-barn, straw-barn, feeding-house for 36 head of cattle, root-house, byre for cows, calf-pens, stable for ten horses, pigs, with yard and troughs, cattle-sheds, dung-beans, and urinarium under, cattle-yards, cart-road paved, rick-yard, mill track, open court, lawn, garden, and orchard.

4168. *A farmery for a turnip soil of from 600 to 900 acres, from the same work, deserves consideration as a very complete specimen of arrangement.* Omitting the farm-house, the economical buildings contain a stable, cow-house, servants' cow, root-house, young horses' stable, straw-barn, corn-barn, stable, cart-shed, place for pickling wheat, killing sheep, or other odd jobs, feeding-house, carpenter's workshop, pigs, geese, common poultry, turkeys, pigs, cattle-sheds, dung and straw courts, with urinarium in the centre of each, paved cart-road round, open court between the yard and dwelling-house, rick-yard, paddocks of old pasture, ponds for drinking and washing the horses' legs.

4169. *The accommodations for a farm-house, suitable to such a design and to the style of life which the person who can occupy such a farm is entitled to enjoy, are as follows.*—In the parlour story there is a lobby, with staircase to chambers and cellars, drawing-room, bedroom, a family work-room, dining-room, business-room, kitchen, barrack-room or manservant's room, store-room, dairy, &c. On the first floor are two best bedrooms, two other bedrooms, bed-closets, another closet, and a water-closet; over are servants' rooms.

4170. *As a farmery for an arable farm near London of 320 acres (Ag. 607), we shall give as an example one erected (with some variations) in the county of Middlesex, in 1810.* It is to be observed, that in Middlesex farming a great object is hay, especially meadow hay, for the London market, which gives rise to the covered spaces for loaded carts (a); it being the custom to load the carts at night, place them under cover, and yoke and go on the road early the following morning. The accommodations of this farmery

607

are, in the dwelling-house, a lobby and stair (a), dining-room (b), drawing-room and green-house (c), a housekeeper's room, nursery or butler's pantry (d), dairy (e), kitchen (f), back kitchen and brew-house (g), gig-house or coach-house (h), small stable (i), harness-room and stair to men's room and hay-loft (k). In the economical buildings are a granary (l), pigs (m), carts or odd articles (n), water-closet (o), poultry (p), litter for the stable (q), stable for twelve horses (r), chaff-room (s), litter (t), room for cutting hay into chaff (u), places for horse food, or straw hay, &c (v), cattle-sheds (w), open colonnade for loaded hay-carts (x), straw end of barn (y), corn-floor (z), unthreshed corn and corn-floor (1), mill course (2), cows (3), cow food (4), calves (5), bailiff's house (6), implements (7), wood-house, coals, &c (8), kitchen-court to master's house (9), garden (10), poultry-yard (11), bailiff's garden (12), lawn, shrubbery, and sheep-walk (13), pond (14), rickyard (15), stack-stands (16), urningum (17).

4171 In the elevations of this farmery (fig 608.), some attention has been paid to effect, by intermingling trees, chiefly oaks, with thorns and honeysuckles.

608

611

4173. An anomalous design for a corn and stall-feeding farm (fig 611) in which the stacks are built on the tops of the stables, cattle, and cart-sheds (c) may be noticed, as pleasing in effect, but not likely to be so useful as the more simple plans. The hay, roots, and straw are stacked in the central circle (b), and very readily supplied to the stable (c), cow-stalls (d), or feeding-yards (e).

612

The threshing-machine (f) is driven by water, which is supplied by a circuitous route (g), from the pond near the house (A). The elevation (fig. 612.) has a good effect when

all the stacks are in their places, and untouched; but as they are removed to the barn the appearance of the flat-roofed sheds will not be so conducive to established notions of beauty and neatness.

4174. *A farmery for a window-farm of 250 acres near London (Ag. 613.), may be arranged as follows:—*The house may contain a porch, lobby, and stair to chambers and

cellars (a), parlour (b), bedroom or study (c), pantry (d), kitchen (e), lumber-room (f), business-room (g), back kitchen (h), coal cellar and maid's room over (i), wood-house (j), yard and pump (k), pigs (m), chaise (n), poultry (o) tools and roots, &c. (p), two stalls, and a saddle and harness place (q), harrows and large implements, &c. (r), bailiff's house or men's lodge (s), cows (t), chaff-cutting room, and granary over (u), straw-barn (v), corn-floor (w), untreshed corn (x), stable and stall for litter (y), loaded or empty carts and implements (z), watering-trough (A), rick-stands (B), bailiff's garden (C), master's garden (D), lawn (E), paddock of old grass (F).

4175. *An anomalous design for a turnip-farm of 500 acres (Ag. 615) contains a dwelling-house (a), on an eminence commanding not only the farmery (b), but great part of the farm. It is surrounded by the ricks for shelter (c), and by a pond (d), which drives the threshing-machines (e), and forms a foreground to the distant scenery. There are a large feeding-shed (f), a bailiff's house and garden (g), and the other usual accommodations. The elevation of the feeding-sheds and end of the barn looking towards the house is simple and not inelegant. (Ag. 614.)* Farmeries of this sort are not sub-

614

mitted as examples for general imitation, but merely as sources of ideas to such as have the designing of this species of rural buildings, for employers who have a taste for design and for originality, and who can afford to gratify that taste. It is a poor business, and one which never can procure much applause, when a proprietor of wealth and cultivated mind erects for his own use the same sort of farmery, or, indeed, of any other buildings, as the tenants who support him. In East Lothian, Berwickshire, Northumberland, and on the Marquis of Stafford's estates both in England and Scotland, are some noble examples of substantial, commodious, and even elegant farmeries. (See Gen. Rep. of Scotland, and Loch & Rep. on the Marq. of Stafford's Estates, &c. 1819.)

SUMMARY. 2. *Laying out Cottages.*

4176. *Cottage buildings* include a variety of habitations from the farm-house downwards. On a large estate there will be cottages for tradesmen and mechanics, with and without fields and gardens, others for market-gardeners and nurserymen, surrounded by gardens and orchards for operative manufacturers for day-labourers and, on the farm lands near the farmhouses, for ploughmen and herdsmen. The extent of ground which ought to accompany these cottages must be determined entirely by the demand: the regular labourer and ploughmen require the least, and the gardener and tradesman, who keep a horse or horses and cow, the most.

616

4177. *A cottage fit for a tradesman, mechanic, or bailiff, given in The General Report of Scotland, contains the following accommodations* — A porch, lobby living-room, two closets with beds, pantry and dairy fuel and lumber-place, pig, and garden. The cow is kept at the farmery if for a bailiff the poultry over the fuel-place, and the bees on stands in the open garden.

4178. *A double cottage of only one floor (fig. 616.) contains in each, the kitchen (a) with oven (b), pantry and dairy (c), lobby (d), two bedrooms (e, e), entrance door (f), front court-yard (g), pigs (h), necessaries (i). The gardens are at each end, and the cows supposed to be kept at the farmery.*

4179. *A cottage on a smaller scale contains the entrance and stair, parlour and bedroom,*

with two good bedrooms over. Behind the main body of the house is a lean-to, containing the kitchen with dairy and pantry, brewing, fuel, and lumber-place. The usual appendages are detached.

4180. *A double cottage for two married ploughmen, given in The General Report of Scotland, contains a porch, and stair to bedrooms, living-room, pantry and dairy, back kitchen, cow or pig-house, gardens, and two good bedrooms to each.*

lour (b) with the usual closets and garret bedrooms. For cottages of upper servants, on the demesne lands of proprietors, Gothic elevations (fig. 620), Chinese, Swiss, and Italian (fig. 621), and every other variety, may be adopted.

4181 *A labourer's cottage with cow-house and piggery (fig. 617), as commonly constructed in the south of Scotland, is thus arranged. — The cow-house (a) and piggery (c) are in a lean-to. The dwelling contains, on the ground floor, an entrance and stair to bed-garret (b), large kitchen and living-room (e) dairy and pantry (d), coal and wood (g), necessary (h).*

4182 *A good mechanic's cottage (fig. 618.) is thus arranged. — Parlour (a) kitchen (b) closet (c) dairy and pantry (d) closet to parlour (e) tool-house (f) poultry (g), back entrance to the kitchen and fuel-place (A) back entrance to house and stair (i) over are two good bedrooms, behind is a small court-yard, and the garden surrounds the whole.*

4183. *Where cottages are erected as picturesque objects, various external forms and styles of design may be adopted, and at the same time the requisite degree of comfort preserved within. Three may be grouped together (fig. 619.) and each have the usual accommodation of kitchen (a) and parlour (b) with the usual closets and garret bedrooms.*

For cottages of upper servants, on the demesne lands of proprietors, Gothic elevations (fig. 620), Chinese, Swiss, and Italian (fig. 621), and every other variety, may be adopted.

4181. *For entrance lodges* there are many elegant designs by Gandy, Robertson, Papworth, and others; some simple and modern, and others in imitation of the older styles of building.

4185. *A very simple entrance lodge of one story* (fig. 681) may contain a kitchen (a), parlour and bed-room opening into it (b), pantry (c) and closet (d). Towards the road there may either be a bow projection or porch. Detached, in the garden, and concealed by trees and shrubs, may be the usual appendages to comfortable cottages.

### SECTION 3. *Laying out the Farm Lands.*

4186. *In arranging farm lands*, the principal considerations are the size and shape of the fields, and the next the access to them and to the farmery by proper roads.

4187. *The form and size of fields* have too often been determined without much regard to the size of the farm, the exposure, and the equability of the soil. This is the more to be regretted in the case of live fences which ought to endure for a long course of years, and which cannot be eradicated without considerable expense. In *The Code of Agriculture* it is observed, that when a whole farm is divided into fields of various sizes, it is difficult to form a plan so as to suit a regular rotation of crops, or to keep very accurate accounts. Whereas, by having the fields *in general* of a large size, the whole strength of a farm and the whole attention of the farmer are directed to one point, while an emulation is excited among the ploughmen, when they are thus placed in circumstances which admit their work to be compared. Some small fields are certainly convenient on any farm, for grazing and other purposes to be afterwards explained. On elevated situations, also, the shelter derived from small enclosures is of use.

4188. *A number of small enclosures*, irregularly shaped, surrounded with trees or high hedges, in corn farms, and more especially in corn lands situated in a flat country where shelter is exceedingly injurious to the farmer. Besides the original expense of making the enclosures, the injury done to the crops of grain produced by the want of a free circulation of air and the harbour afforded to numbers of small birds, the very site of numerous hedges, with their attendant ditches, and the uncultivated slips of land on both sides of them, consume a much larger proportion of arable land than is commonly imagined. Hedges, especially if accompanied by rows of trees, greatly exhaust the ground of its fertility nourish weeds, the seeds of which may be widely disseminated and by the exclusion of air the harvesting of the crop is carried on more slowly. Even upon meadow land, small enclosures surrounded by hedges are injurious, as they prevent the circulation of air for making or drying the hay. Small enclosures, with high hedges and trees, are also extremely injurious to the roads in their neighbourhood.

4189. *With fields of a considerable size* less ground is wasted, and fewer fences are to uphold. The crops of grain, being more exposed to wind, can be harvested earlier and they suffer less from damp seasons. Small enclosures in pasture are more productive in winter, being better sheltered, but in summer the larger and more open enclosures are the better, for in hot weather both cattle and sheep always resort to the most airy places. It is easier, also, when they are in pasture, to obtain a supply of water in large fields than in small ones. Indeed, fields are sometimes so small, that it is very difficult to procure an adequate supply of water even in winter. But the conclusive argument in favour of large arable fields is this, that where fields are small, much time and labour are wasted by short turnings, and it is now ascertained "that if fields are of a regular shape, and the ridges of a proper length, five ploughs may do as much work as six ploughs in fields of a small size and of an irregular shape while every other branch of labour (such as dunging sowing harrowing reaping and carrying in the harvest) can be executed, though not altogether yet nearly in the same proportion" (*Trans. of Soc. vol. I. p. 41. and Sup. Memo. Hist. art. Agr.*)

4190. *The circumstances on which the use of fields ought to depend* are, the extent of the farm in which they are situated, the nature of the soil and subsoil, the rotations adopted, the inclination of the ground, its being in pasturage or otherwise, and the nature of the climate. (*Code.*)

4191. *Extent of the farm.* The size of fields ought certainly in some measure, to depend upon the extent of the possession. In small farms near towns, from six to twelve acres may be sufficient, but where farms are of a considerable extent, fields from twenty to even fifty acres, and, in some particular cases, as high as sixty may be used to advantage. In general, however even on large farms, when permitted by local circumstances fields of a medium size, as from fifteen to twenty five English acres, are recommended by competent judges.

4192. *Soil and aspect.* In dividing a farm into fields, the nature of the soil and subsoil ought to be kept in view. Where the soil is various, it would be proper to separate the light from the heavy. They are not only better calculated for different crops and different rotations, but are naturally adapted to be cultivated at different seasons. It is unfortunate, therefore, to have soils of a heterogeneous nature mingled in the same field. But where this partially takes place, for instance, where there is only an acre or two of light soil to ten or twenty of strong soil, let the following plan be adopted. — At any slack time, either in summer or winter more especially when the field is under fallow, employ two carts and horses with four oxen, to cover the acre or two of light soil, with the strong soil contiguous, and the soil in the field will then become more uniform. In fields where light soils predominate, the plan might be reversed. This plan, though at first expensive is attended with such advantages that, whenever it is necessary and practicable, it ought to be carried into effect.

4193. *The rotation adopted.* It may be considered as a good general rule, to divide a farm according to the course of crops pursued in it; that is to say, a farm with a rotation of six crops should have six fields or twelve, according to circumstances. It is proper to have a whole field, if the soil be uniform, under one crop; and every farmer of experience knows the comfort of having the produce of the farm as equal every year as the soil and season will admit of.

4194. *Division of the ground.* It is, however, evident that the size of the fields must in some respects depend on the nature or the hilly shape of the ground. Even on dry land, if there be a rise on the ground, from fifteen to twenty chains is sufficient length; for if the ridge be longer, the horses become much fatigued if compelled to plough a strong furrow uphill beyond that length in one direction. This objection, however to large fields, may in some measure be obviated, by giving the ridges and furrows in such fields as are on the sides of a hill, such an obliquity as may diminish the steepness of the ascent.

**4185. Pastureage.** Where the system of getting and tilage alternately is followed (more especially where the fields are pastured for two or three years in succession), it is convenient to have the fields of great extent to pasture thick shaggy swards. The farmer is thus enabled to divide his stock, which he cannot well do with larger fields. The cattle or sheep remain more quiet than if a greater number were collected together, and less grass is destroyed by treading. When such a field has been pastured for some time, the stock should be removed to another till the grass in the former has renewed, and is fit for being eaten. Such a size also, in general, suits grangers better than larger ones, and consequently fields of this extent, when in pasture, generally let for more rent.

**4186. Climate.** The last consideration to be considered, in determining the proper size of fields, is the nature of the climate. In dry and cold climates, small enclosures are desirable on account of shelter whereas, in wet countries, the fields under culture cannot be too open and airy for the purpose of drying the ground, of bringing forward and ripening the grain, and of enabling the farmer more easily to secure it during an unfavorable harvest, by having a free circulation of air. But, though on large farms fields should in general be formed on an extensive scale, yet there is a convenience in having a few smaller fields near the farm house for keeping the family cows for turning out young horses, mares, and foals for raising a great variety of vegetables and for trying experiments on a small scale which may afterwards be extended, if they shall be found to answer. When enclosures are too large for particular purposes, and where no small fields, as above recommended, have been prepared, large fields may be subdivided by sheep-hurdles, a sort of portable fence well known to every turnip-grower. In this way great advantage may be derived from the constant use of land that would otherwise have been occupied by stationary fences, and the expense of subdivisions, which on a large farm, would necessarily have been enormous, is thereby avoided. This fence is perfectly efficient against sheep, though it is not so well calculated for stronger animals.

**4197. The shape of fields may be either square or oblong.**

**4198. Square fields.** The advantage of having the fences in straight lines, and the fields, when large, of a square form, is unquestionable, as the ploughing of them under this arrangement can be carried on with much greater despatch, fewer turns, whose fields are of a waving or uneven shape, and who enclose with hedge and ditch, carry their fence through the fields, or bend and, with a view of making a good hedge, thus often sacrificing, for the sake of the fence, the form of their field. A straight line, however, is preferable, even though it should be necessary to take some particular pains to enrich the soil for the hedge, where it is thin and poor on any elevation. By means of the square form, an opportunity is afforded of ploughing in every direction, when necessary, and less time is lost in carrying on all the operations of husbandry in a field of that form than of any other. When the waving form is necessary to secure proper water runs, plantations may be so disposed as to reduce the fields to squares or oblongs, and the fences to straight lines. Rectangular fields have another advantage, that in fields of that shape it may be known whether the ploughmen have performed their duty, the quantity of work done being easily calculated from the length and breadth of a certain number of ridges.

**4199. Oblong fields.** When fields are small, an oblong shape should be preferred, that the ploughings may be completed with as few turnups as possible. This form has also other advantages: the fields are more easily subdivided, and water can in almost every case be got, by making proper ponds in the meadows or joining of these or four fields, whose gutters or ditches will convey water to the ponds. In turnip soils where the shape is oblong, it is easier to divide the turnips with nets or hurdles, for the convenience of feeding them off with sheep. If the ridges are too long, and the field dry and level, the length may be reduced by making cross head-lands, or head-ridges, at any place that may be considered the fittest by the occupier. (*Code of Agr. 128 to 137*)

**4200. Hedge-row trees** are very generally objected to by agriculturists. Notwithstanding the garden-like appearance which they give to the landscape, "it seems to be agreed by the most intelligent agriculturists that they are extremely hurtful to the fence, and for some distance to the crops on each side and it is evident, that in many instances the high-ways, on the sides of which they often stand, suffer greatly from their shade. It has therefore been doubted whether such trees be profitable to the proprietor or beneficial to the public to the farmer they are almost in every case injurious, to a degree beyond what is commonly imagined." (*Supp. to Encyc. Brit. art. Agr.*)

**4201. The opinion of Lock,** a well informed and unprejudiced improver of landed property is of an opposite description. He says "There is no change in the rural economy of England more to be regretted, than the neglect which is now shown to the cultivation and growth of hedge-row timber. The inquiry which it does to the cultivation of the land is much exaggerated, especially if a proper selection of trees is made: but even the growth of the ash, so formidable to agriculturists, might be defended on the ground that without it the best implements employed in the cultivation of the soil could not be made. It is well known that good hedge-row timber is by far the most valuable both for naval and domestic purposes: its superior toughness rendering it equally valuable to the ship-builder and to the ploughwright. The value which it is of in affording shelter is also material besides, the raising of grain is not the only purpose of life, or the only matter to be attended to, nor the only object worthy of attention. The purposes of war and of national glory, the protection and extension of our commerce, the construction and repair of buildings, and even the enjoyment arising from the rich and beautiful effect produced by such decoration and ornament, are all objects of material importance to the well-being and constitution of a highly cultivated state of society. Even upon the more narrow basis of individual utility this practice might be defended and recommended for it is not useless to consider how many families and estates have been preserved, whose present by temporary destruction (from which hope are exempted) by a fall of hedge-row timber. One of the best families which a great proprietor can leave his country and his family, is an estate well stocked with such trees." Believing, as we do, that there can be no real and permanent beauty that is inconsistent with utility we prefer, for arable lands, hedges wholly without timber trees. In pasture lands we would rather see the trees in scattered groups than in the hedges, because so placed they are only injurious to the pasture, whereas in the hedges they are injurious to that and the pasture also.

**4202. The gates of fields** should in most cases be placed in the middle of that side of the field which is nearest the road, because, in carting home produce, or in carting out manure, the labour of carting is less on a road than on the soft ground of the field, and because such carting always more or less injures this ground; a part of it along the head-lands being necessarily subjected to repetition in the same track; and not in an angle, or at one corner, unless particular circumstances point out this as the preferable mode. Some contend that the gates of fields should be placed in or near the corner next to the road or homestead; but our objection to this arrangement is, that, in carting out manure, or carting home the crop, the headland is liable to be much more severely injured by cart runs than when the gate is in the middle.

4203. The *drainage and water-courses*, if any, on farm lands, require to be attended to in laying out the fences, so as if possible to make the ditches of the latter serve as open drains also, when opportunity offers, for conveying streams to be used in irrigation, or for driving machinery. The fences and roads will, to a certain extent, be guided by the course of such stream or streams.

4204. As an example of laying out farm lands from a newly enclosed common, we submit the case of a flat surface, a strong retentive clay soil, a moist climate, a situation distant from markets, with no other object in view than that of making as much of the lands as possible.

4205. A public road (Ag. 223. a) passes the farm, and the farmery is approached by a private road (b).

The use of the farm deemed proper is 850 acres the most profitable mode of occupation is, 180 in arable, and the remainder in pasture. The arable subjected to a rotation of 1st, beans drilled, or naked fallow dunged; 2d, wheat 3d, clover and rye-grass, fed off or mown for soiling cattle 4th, wheat or oats, if the clover was mown, dunged. The grass-lands are supposed to be wholly fed off, chiefly with cattle, but also with ten cows, for butter and breeding, and a few sheep.

4206. The buildings (c) are placed in the centre of the farm, and contain stabling for four work-horses, and open sheds for eight oxen 150 feet of shade for thirty fattening cattle; a barn, with threshing-machine impelled by wind; houses for ten cows, and other conveniences in proportion. There is a kitchen-garden, orchard, rack-yard, and two paddocks (d, e, f), adjoining the farmery.

4207. The grass-fields (g), contain only ten acres each to admit of the great advantage of shifting the stock from one to another. They are most distant from the farmery because requiring least cartage; and some of them being in the lowest part of the farm, they may be irrigated. Trees are avoided in the fences, as injurious in flat surfaces and adhesive soils. For the purpose of shading cattle, one or two might be planted in the angles of the field; but a temporary shed of the rudest and slightest materials, and easiest taken down, removed, and reconstructed, is preferable, as calculated to distribute the manure produced by the cattle when at rest.

4208. The arable lands (h) are preserved in the centre, to save carting to and from the farmery, and the enclosures are four times the size of the grass-fields, each shift forming one large enclosure, containing four fields, divided only by open ditches for carrying off the surface water. The two small central fields shown under aration, are supposed alternately in turnips, potatoes, cabbages, &c. for cows, &c. and wheat. The paddocks and steers are for calves or colts.

4209. The chief, and almost sole, products of the farm will be wheat and beef the former best worth sending to a distant market, the latter easily transported to any distance and both staple commodities.

4210. With respect to roads, sometimes a farm is situated on both sides of a highway in which case all the fields may be made to open into it, either directly or through an intervening field. Hence no private road is wanting, excepting a few yards to reach the farmery. But when, as is most generally the case, the lands are situated at a distance from a great road, and approached by a lane or by road, then from that by-road a private road is required to the farmery, and a lane or lanes from it so contrived as to touch at most of the fields of the farm. In wet and clayey soils, these lanes must be formed of durable materials, but in dry soils, provided attention be paid to fill in the cart-ruts as they are formed (by the landing out of dung, or horse or corn) with small stones, gravel or even earth, the lane may remain grass; and, being grazed by sheep or cattle, will not be altogether lost. It is essentially necessary to make a piece of road at the gate of every enclosure, the being the spot which is most frequently in use. Without this precaution, it often becomes a wire where corn is thrown down and spoiled in harvest, or, if it is attempted to avoid the wire, the gate-posts and neighbouring fence are often damaged. (Communications to the Board of Agriculture, vol. II. p. 251.)

4211. *Wet and peaty soils a farmer will perform his operations at much less expense; the labour of the horses will be much easier; a greater quantity or weight of grain and other articles may be more easily carried over them; manure can be more easily conveyed to the fields; the harvest can be secured at more rapidly; and wear and tear of every description will be greatly reduced. (Code of Agr. culture, p. 165.)*

### BOOK III

#### OF IMPROVING THE CULTURABLE LANDS OF AN ESTATE.

4212. *HAVING completed the general arrangement of an estate, the next thing is to improve the condition of that part of it destined to be let out to tenants, which, as already observed, constitutes the chief source of income. The farm lands being enclosed and subdivided, and the farmhouses and cottages built in their proper situations, in many cases no other improvements are wanted on the soil than such as are given by the tenant in the ordinary course of culture. But there are also numerous cases, in which improvements are required which could not be expected from an occupier having only a temporary interest in his possession; and these form the present subject of discussion. Such improvements are designated by agriculturists permanent, as conferring an increased purchasable value on the property in opposition to improvements by a temporary occupier the benefits of which are intended to be reaped during his lease. The latter class of improvements includes fallows, liming, marling, manuring, improved rotations, and others of greater expense, according to the length of lease rent, and encouragement given by the landlord: the former, which we are now about to discuss, includes draining, embanking, irrigating, bringing waste lands into cultivation, and improving the condition of lands already in a state of culture.*

#### CHAP. I.

##### *Draining Watery Lands.*

4213. *Draining is one of those means of improvement, respecting the utility of which agriculturists are unanimous in opinion. Though practised by the Romans (143.), and in all probability in some cases by the religious fraternities of the dark ages, it was not till after the middle of the last century that its importance began to be fully understood in Britain and that some individuals, and chiefly Dr. Anderson and Elkington, began to practise it on new principles. About the same time the study of geology became more general, and this circumstance led to the establishment of the art on scientific principles. The public attention was first excited by the practice of Elkington, a farmer and self-taught professor of the art of draining in Warwickshire and the adjoining counties. On the practice of this artist most of the future improvements have been founded and they have been ably embodied in the account of his practice by Johnston, from whose work we shall draw the principal materials of this section, borrowing also from the writings of Dr. Anderson, Marshall, Smith, Farey, Stephens, and some others on the same subject, and from the sixth and seventh volumes of the *Highland Society's Transactions*. After submitting some general remarks on the natural causes of wetness in lands, we shall consider in succession the drainage of boggy lands, hilly lands, mixed soils, retentive soils, and mines and quarries, and then the kinds of drains, and draining materials.*

##### *SECT. I. Natural Causes of Wetness in Lands, and the general Theory of Draining*

4214. *The successful practice of draining in a great measure depends on a proper knowledge of the structure of the earth's upper crust, that is, of the various strata of which it is composed, as well as of their relative degrees of porosity, or capability of admitting or rejecting the passage of water through them, and likewise of the modes in which water is formed, and conducted from the high or hilly situations to the low or level grounds. In whatever way the hills or elevations that present themselves on the surface of the globe were originally formed, it has been clearly shown, by sinking large pits, and digging into them, that they are mostly composed of materials lying in a stratified order and in oblique or slanting directions downwards. Some of these strata, from their nature and properties, are capable of admitting water to percolate or pass through them while others do not allow it any passage, but force it to run or filtrate along their surfaces without penetrating them in any degree, and in that way conduct it to the more level grounds below. These strata become obstructed or checked up by meeting with impervious materials of some kind or other, by which it is readily forced up into the superincumbent layers where they happen to be open and porous, soon rendering them too wet for the purpose*

of agriculture but where they are of a more tenacious and impenetrable quality they only become gradually softened by the stagnant water below them; by which the surface of the ground is, however, rendered equally moist and swampy, though somewhat more slowly than in the former case. It may also be observed, that some of the strata which constitute such hilly or mountainous tracts are found to be continued with much greater regularity than others these which are placed nearest to the surface, at the inferior parts of such hills or elevations, being mostly broken or interrupted before they reach the tops or higher parts of them while those which lie deeper, or below them at the bottom, show themselves in these elevated situations. Thus, that stratum which may lie the third or fourth, or still deeper at the commencement of the valley may form the uppermost layer on the summits of hills or mountainous elevations. This arrangement or distribution of the different strata may have been produced partly by the circumstances attending the original elevation of such mountainous regions, and partly from the materials of the original exterior strata being dissolved and carried down into the valleys by successive rains and other causes, and thus leaving such as were immediately below them in an exposed and superficial state in these elevated situations. (*Darwin's Phytologia*, p. 258.)

4215 These elevated strata frequently prove the means of rendering the grounds below wet and swampy; for the general moisture of the atmosphere being condensed in much greater quantities in such elevated situations, the water thus formed as well as that which falls in rain and sinks through the superficial porous materials, readily emanates itself and thus passes along between the first and second or still more inferior strata which compose the sides of such elevations, until its descent is retarded or totally obstructed by some impenetrable substance such as clay it then becomes dammed up, and ultimately forced to filtrate slowly over it, or to rise to some part of the surface, and constitute, according to the particular circumstances of the case, different watery appearances in the grounds below These appearances are, oozing springs, bogs, swamps, or morasses weeping rocks from the water slowly issuing in various places, or a large spring or rivulet from the union of small currents beneath the ground. This is obvious from the sudden disappearance of moisture on some parts of lands, while it stagnates, or remains till removed by the effects of evaporation on others as well as from the force of springs being stronger in wet than in dry weather breaking out frequently after the land has been impregnated with much moisture in higher situations, and as the season becomes drier ceasing to flow except at the lowest outlets. The force of springs, or proportion of water which they send forth depends likewise in a great measure, on the extent of the high ground on which the moisture is received and detained, furnishing extensive reservoirs or collections of water by which they become more ample and regularly supplied. On this account what are termed bog-springs, or such as rise in valleys and low grounds, are considerably stronger and more regular in their discharge, than such as burst forth on the more elevated situations or the sides of eminences. (*Johnston's Account of Ellington's Mode of Draining Land* p. 15)

4216 The waters condensed on elevated regions are sometimes found to descend for a very considerable distance, among the porous substances between the different conducting layers of clayey or other materials, before they break out or show themselves in the grounds below but they are more frequently found to proceed from the contiguous elevations into the low grounds that immediately surround them.

4217 The nature of the stratum of materials on which the water descending from hills has to proceed must considerably influence its course, as well as the effects which it may produce on such lands as lie below, and into which it must pass. Where the stratum is of the clayey stiff marly, or impervious rocky kind, and not interrupted or broken by any other materials of a more porous quality the water may pass on to a much greater distance, than where the stratum has been frequently broken and filled up with loose porous materials, in which it will be detained, and of course rise up to the surface.

4218 These sorts of strata extend to very different depths in different directions and districts, as it has been frequently noticed in the digging of pits, and the sinking of deep wells, and other subterraneous cavities. The clayey strata are, however, in general found to be more superficial than those of the compact, tenacious, marly kind, or even those of a firm, uninterrupted, rocky nature, and seldom of such a great thickness; they have, nevertheless, been observed to vary greatly in this respect, being met with in some places of a considerable thickness, while in others they scarcely exceed a few inches.

4219 The intervening porous substances, or strata, where clay prevails, are found, for the most part, to be of either a gravelly or loose rocky nature. Stiff marly strata, which approach much to the quality of clay though in some instances they may present themselves near the surface, in general lie concealed at considerable depths under the true clayey strata, and other layers of earthy or other materials they have been discovered of various thicknesses, from eight or ten feet to considerably more than a hundred. (*Darwin's Phytologia*, p. 258.) The intervening materials, where strata of this nature predominate, are most commonly of the more sandy kinds possessing various degrees

of induration, so as in some cases to become perfectly hard and rocky, but with frequent breaks or fissures passing through them. The loose, friable, marly strata are capable of absorbing water, and of admitting it to filtrate and pass through them.

4230. Thus the valleys and more level grounds must constantly be liable to be overcharged with moisture, and to become, in consequence, spouty, boggy, or of the nature of a morass, accordingly as they may be circumstanced in respect to their situation, the nature of their soils, or the materials by which the water is obstructed and detained in or upon them.

4231. Where lands have a sufficient degree of elevation to admit of any over-proportion of moisture readily passing away and where the soils of them are of such a uniform sandy or gravelly and uninterrupted texture, as to allow water to percolate and pass through them with facility they can be little inconvenienced by water coming upon or into them, so it must of necessity be quickly conveyed away into the adjacent rivers or small runlets in their vicinity.

4232. But where grounds are in a great measure flat and without such degrees of elevation as may be sufficient to permit those over-proportions of moisture that may have come upon them from the higher and more elevated grounds to pass readily away and be carried off, and where the soils of the lands are composed or constituted of such materials as are liable to admit and retain the excesses of moisture they must be exposed to much injury and inconvenience from the retention and stagnation of such quantities of water. Such lands consequently require artificial means to drain and render them capable of affording good crops, whether of grain or grass.

4233. Lands of valleys and other low places, as well as, in some cases, the level tracts on the sides or borders of large rivers and of the sea must also frequently be subject to great injury and inconvenience from their imbibing and retaining the water that may be thus forced to flow up into or upon them, either through the different conducting strata from the hills and mountainous elevations in the neighbourhood or the porous materials of the soils. In these ways they may be rendered swampy, and have bogs or morasses produced in them in proportion to the predominancy of the materials by which the water is absorbed and dammed up, and the peculiarity of the situation of the lands in respect to the means of conveying it away.

4234. To perform properly the business of draining, attention should not only be paid to the discrimination of the differences in regard to the situation of the lands, or what is commonly denominated drainage level but also to the nature, distribution, and depth of the materials that constitute the soils or more superficial parts of them, as upon each of these some variety, in respect to the effects arising from water retained in them, may depend.

4235. The general origin of that wetness of land which it is the object of under-draining to remove, "will be found to be the existence of water in substrata of sand, gravel, open rock, or other porous substances, which either lead to the surface, or, having no natural outlet, become filled or saturated, while the pressure of more water coming from a higher source, forces that which is in the lower part of the stratum upwards through the superior strata to the surface; thus occasioning either bursts and springs, or a general oozing through the soil. The object in under-draining therefore, is not to catch the surface-water but that which flows through their inferior strata, and, for this purpose, it is necessary to make a sufficient channel, either at the lower parts of the porous stratum, or in such part of it as may most conveniently carry off the water so as the pressure referred to may be relieved, or the water intercepted before it reaches the surface. It must always be kept in mind, then, that under-draining and surface-draining are operations essentially distinct and every care must be used in practice not to blend them in the execution. If surface-water be allowed to get into covered drains, the sand and mud which it will carry into these subterraneous channels will soon choke them up, and occasion bursts, creating, as may be conceived, new swamps while the expense of taking up and relaying the under-drains will be very great, and the execution imperfect, the dikes being found never to stand a second time so well as when first formed." (*Highland Society's Trans.* vol. vii. p. 216.)

4236. Wetness of land, so far as it respects agriculture, and is an object of draining, may generally depend on the two following causes first, on the water which is formed and collected on or in the hills or higher grounds, filtrating and sliding down among some of the different beds of porous materials that lie immediately upon the impervious strata, forming springs below and flowing over the surface, or stagnating underneath it; and, secondly, on rain or other water becoming stagnant on the surface, from the retentive nature of the soil or surface materials, and the particular nature of the situation of the ground. The particular wetness which shows itself in different situations, in the forms of bogs, swamps, and morasses, for the most part proceeds from the first of these causes; but that superficial wetness which takes place in the stiff, tenacious, clayey soils, with little inclination of surface, generally originates from the latter.

4237. The most certain and expeditious method of draining, in such cases, is that of

intercepting the descent of the water or spring, and thereby totally removing the cause of wetness. This may be done where the depth of the superficial strata, and consequently of the spring, is not great, by making horizontal drains (fig. 624. a) of con-

derable length across the declivities of the hills, about where the low grounds of the valleys began to form, and connecting these with others (b) made for the purpose of conveying the water thus collected into the brooks or runlets (c) that may be near. Where the spring has naturally formed itself an outlet, it may frequently only be necessary to bore into it (c), or render it larger, and of more depth which, by affording the water a more free and open passage, may evacuate and bring it off more quickly, or sink it to a level so greatly below that of the surface of the soil, as to prevent it from flowing into or over it.

4228. Where the uppermost stratum is so extremely thick as not to be easily penetrated, or where the springs, formed by the water passing from the higher grounds, may be confined beneath the third or fourth strata of the materials that form the declivities of hills or elevated grounds, and by this means lie too deep to be penetrated to by the cutting of a ditch or even by boring (*Darwin's Phytologia*, p. 263.), the common mode of cutting a great number of drains to the depth of five, six, or more feet, across the wet morassy grounds, and afterwards covering them in such a manner as that the water may suffer no interruption in passing away through them, may be practised with advantage, as much of the prejudicial excess of moisture may by this means be collected and carried away though not so completely as by fully cutting off the spring.

4229. As water is sometimes found upon thin layers of clay, which have underneath them sand, stone, or other porous or fissured strata, to a considerable depth by perforating these thin layers of clay in different places, the water which flows along them may frequently be let down into the open porous materials that lie below them, and the surface land be thus completely drained.

4230. Where morasses and other lands of wetness are formed in such low places and hollows as are considerably below the beds of the neighbouring rivers, they may probably, in many instances, be effectually drained by arresting the water as it passes down into them from the higher grounds, by means of deep drains cut into the sides of such hills and rising grounds, and, after collecting it into them conveying it away by pipes, or other contrivances, at such high levels above the wet lands as may be necessary or where the water that produces the mischief can, by means of drains, cut in the wet ground itself, be so collected as to be capable of being raised by means of machinery, it may in that way be removed from the land.

4231. The drainage of lands that lie below the level of the sea can only be effected by the public, and by means of locks erected for the purpose of preventing the entrance of the tides, and by windmills and other expensive kinds of machinery constructed for the purpose of raising the stagnant water.

4232. The superficial wetness of lands, which arises from the stiff retentive nature of the materials that constitute the soils and the particular circumstances of their situations, is to be removed in most cases by means of hollow surface drains, judiciously formed, either by the spade or plough, and filled up with suitable materials where the lands are under the grass system; and by these means and the proper construction of ridges and furrows where they are in a state of arable cultivation.

4233. Having thus explained the manner in which soils are rendered too wet for the purposes of agriculture, and shown the principles on which the over-proportions of moisture may under different circumstances, be the most effectually removed, we shall proceed to the practical methods which are to be made use of in accomplishing the business in each case.

#### Book II. The Methods of Draining Buggy Land.

4234. In the drainage of wet or buggy grounds, rising from springs of water beneath them, a great variety of circumstances are necessary to be kept in view. Lands of this

description, or such as are of a marshy and boggy nature, from the detention of water beneath the spongy surface materials of which they are composed, and its being absorbed and forced up into them, are constantly kept in such states of wetness as are highly improper for the purpose of producing advantageous crops of any kind. They are, therefore, on this account, as well as from their occupying very extensive tracts in many districts, and being, when properly reclaimed, of considerable value, objects of great interest and importance to the attentive agriculturist. Wet grounds of these kinds may be arranged under three distinct heads: first, such as may be readily known by the springs rising out of the adjacent more elevated ground, in an exact or regular line along the higher side of the wet surface; secondly, those in which the numerous springs that show themselves are not kept to an exact or regular line of direction along the higher or more elevated parts of the land but break forth promiscuously throughout the whole surface, and particularly towards the inferior parts (*fig. 625. c*) constituting shaking quags in every direction, that have an elastic feel under the feet, on which the lightest animals can scarcely tread without danger, and which, for the most part, show themselves by the luxuriance and verdure of the grass about them; and, thirdly that sort of wet land, from the noising of springs, which is neither of such great extent, nor in the nature of the soil so peaty as the other two, and to which the term *bog* cannot be strictly applied, but which in respect to the modes of draining is the same. (*Johnston's Account of Edinburgh's Mode of Draining Land*, p. 19.)

4235. In order to direct the proper mode of cutting the drains or trenches in draining lands of this sort, it will be necessary for the draining engineer to make himself perfectly acquainted with the nature and disposition of the strata composing the higher grounds, and the connection which they have with that which is to be rendered dry. This may in general be accomplished by means of levelling and carefully attending to what has been already observed respecting the formation of hills and elevated grounds, and by in-

625

specting the beds of rivers, the edges of banks that have been wrought through, and such pits and quarries as may have been dug near to the land. Rushes, alder-bushes, and other coarse aquatic plants, may also, in some instances, serve as guides in this business but they should not be too implicitly depended on, as they may be caused by the stagnation of rain-water upon the surface, without any spring being present. The line of springs being ascertained, and also some knowledge of the substrata being acquired, a line of drain (*fig. 625. b, b*) should be marked out above or below them, according to the nature of the strata, and excavated to such a depth as will intercept the water in the porous strata before it rises to the surface. The effect of such drains will often be greatly heightened by boring holes (*c*) in their bottom with the auger. Where the impervious stratum (*fig. 626. e*), that lies immediately beneath the porous (*b*), has a slanting direction

626

through a hill or rising bank, the surface of the low lands will, in general, be spongy, wet, and covered with rushes on every side (*c*). In this case, which is not unfrequent, a diach or drain (*a*), properly cut on one side of the hill or rising ground, may remove

the wetness from both. But where the impervious stratum dips or declines more to one side of the hill or elevation than the other the water will be directed to the more depressed side of that stratum the effect of which will be, that one side of such rising ground will be wet and spongy, while the other is quite free from wetness.

4256 *Here aoter issues forth on the surface at more places than one*, it is necessary to determine which is the real or principal spring, and that from which the other outlets are fed as by removing the source, the others must of course be rendered dry. When on the declivity or slanting surface of the elevated ground from which the springs break forth, they are observed to burst out at different levels according to the difference of the wetness of the season, and where those that are the lowest down continue to run while the higher ones are dry, it is, in general, a certain indication that the whole are connected, and proceed from the same source, and consequently that the line of the drain should be made along the level of the lowermost one, which, if properly executed, must keep all the others dry. But if the drain were made along the line of the highest of the outlets, or places where the water breaks forth, without being sufficiently deep to reach the level of those below, the overflows of the spring would merely be carried away, and the wetness proceeding from that cause be removed while the main spring, still continuing to run, would render the land below the level of the bottom of the drain still prejudicially wet, from its discharging itself lower down over the surface of the ground. Thus, Johnston states, was the custom, until Elkington showed the absurdity of the practice of drainers beginning to cut their trenches wherever the highest springs showed themselves between the wet and the dry ground, which not being of a depth sufficient to arrest and take away the whole of the water, others of a similar kind were under the necessity of being formed at different distances, to the very bottom of the declivity these being afterwards in a great measure filled with loose stones, merely conveyed away portions of surface water, without touching the spring the great or principal cause of the wetness. The effects of drains formed in this manner he asserts to be that of rendering the surface of the land in some degree drier so long as they continue to run with freedom but as they are liable soon to be obstructed and filled up by sand or other materials, the water is often forced out in different places and directions, and thus renders the land as wet as before if not wetter. In addition to this, it is a more difficult task to drain the ground a second time in a proper method, from the natural appearance of the ground being so much changed, and the bursts of the old drains, as well as the greater difficulty of ascertaining the real situation of the springs.

4257 *It may sometimes happen, however, that where the highest are the strongest outlets, they may be the main or leading springs*; those which show themselves lower down in the land being merely formed by the water of the main spring overflowing, and finding itself a passage into the earth through an opening in the surface, or through the porous materials of the soil near to the surface, and being obstructed somewhat further down in the ground by some impervious stratum. This circumstance must, therefore, it is observed, be fully ascertained before the lines for the ditches or drains are marked out.

4258. *In cases where the banks or rising grounds are formed in an irregular manner* (fig. 647), and, from the nature of the situation, or the force of the water underneath,

627

springs abound round the bases of the protuberances, the ditches made for the purpose of draining should always be carried up to a much higher level in the side of the elevated ground than that in which the water or wetness appears as far even as to the firm unchanged land. By this means the water of the spring may be cut off and the ground completely drained which would not be the case if the trench or drain were formed on the knee of the loose materials lower down, where the water comes out, which is liable to mislead the operator in forming the conducting trench, or that which is to convey the water from the cross-drain on the level

of the spring to the outlet or opening by which it is discharged. But where the main or principal spring comes out of a perpendicular or very steep bank, at a great height above the level of the outlet into which it may discharge itself by means of a drain, it will neither be necessary nor of any utility to form a deep trench, or make a covered drain, all the way from such outlet up to it as from the steepness of the descent the water

would be liable, when the drain was thus cut, from the thin strata of sand and other loose materials, always found in such cases, to insinuate itself under the bricks, stones, or other substances of which the drain was formed; to undermine and force them up by the strength of the current, or probably, in some instances, block the drain up by the loose sand or other matters, which may be forced away and carried down by it. In situations of this kind, Johnston observes, it is always the best way to begin just so far down the bank or declivity as, by cutting in a level, the drain may be six or seven feet below the level of the spring; or of such a depth as may be requisite to bring down the water to a level suitable to convey it away without its rising to the surface, and injuring the lands around it. The rest of the drain, whether it be made in a straight or oblique direction, need not be deep, and may, in many instances, be left quite open, it should, however, be carefully secured from the treading of cattle, and, where the land is under an arable system of cultivation, also from the plough. Where it is covered, the depth of about two feet may be sufficient. There will not, in such drains, be any necessity for the use of the auger in any part of them.

4339. *Where there is a difficulty in ascertaining the line of the spring* and consequently that of the cross-drain either from its not showing itself on the surface, or from there not being any apparent outlet, it may, generally be met with in carrying up the conducting drain for conveying away the water. As soon as the operator discovers the spring, he need not proceed any further, but form the cross-drain on the level thus discovered to such a distance on each side of the tail, or terminating part, of the strata, of whatever sort, that contains the water, as the nature of the land, in regard to situation or other circumstances, may demand. Where, in forming a cross-drain, the line indicated by the spurt or other level is found to be in some places below that of the spring, and where, in boring in this direction, water is not found to follow, it will be necessary to make short drains or cuts of the same depth with the cross-drain, from it quite up to the source of the spring for if the drain be cut below the line of the spring, the possibility of reaching it by means of an auger is lost, as where the under stratum is clay and there is no under water the use of the auger cannot be effectual; and if it be made above the line of the spring, it will be requisite to cut and bore much deeper in order to reach it, the ground being in general higher in that part besides, the portion of porous stratum below the drain may contain a sufficient quantity of water to render the land wet, and that may readily get down underneath the trench, between the holes formed by boring, and break out lower down.

4340. *In situations where the extent of bog in the valley between two banks or eminences is so narrow and limited as that the stratum of rock, sand, or other materials, that contains the water, may unite below the clay at such a depth as to be readily reached by the auger* (fig. 623. a) it will seldom be necessary to have more than one trench up the middle,

623

well perforated with holes (b) by means of the auger, cross or branching drains being unnecessary in such cases. For notwithstanding the springs, that render the land injuriously wet in these cases, burst out of the banks or eminences on every side, for the most part nearly on the same level, the reservoir from which they proceed may be discovered in the middle of the valley, by penetrating with the auger through the layer of clay that confines and forces the water to rise up and come out round the superior edge of it, where it forms a union with the high porous ground. From the drain being made in the hollowest part of the land, and the porous stratum containing the water being thus bored into, it is obvious that, the ditch or drain thus formed being so much lower than the ordinary outlet of the springs, the pressure of water above that level, which is the bottom of the drain, must be such as to force that which is under the drain or trench through the holes made by the auger, and in many instances, until a considerable quantity of the

water is evacuated, make it rise to a greater height than the level of its natural outlet. The effect of which must be, that the water forming the spring, having found by these means a fresh and more easy passage, will quickly relinquish its former openings, and thus be prevented from running over and injuring the ground that previously lay lower down than it.

1241 *But in swamps or bogs that are extensive and very wet* other drains or cuts than such as convey off the springs must be made, as, notwithstanding the higher springs which chiefly cause the wetness may be intercepted, there may be lower veins of sand, gravel, or other porous materials, from which the water must likewise be drawn off. In cases of this nature, where the land is to be divided into enclosures, the ditches may be formed in such directions as to pass through and carry off collections of water of this kind, as well as those that may be retained in the hollows and depressions on the surface of the land. There are in many places very extensive tracts of ground that are rendered wet, and become full of rushes and other coarse plants, from causes of such a nature as cannot be obviated by the making of either open or covered drains, however numerous they may be. Lands in this situation are frequently termed *bolms*, and mostly lie on the sides of such rivers and brooks as, from the frequency of their changing and altering their courses between their opposite banks, leave depositions of sand, gravel, and other porous materials, by which land is formed, that readily admits the water to filtrate and pass through it to the level of the last-formed channels, and which preserves it constantly in such a state of moisture and wetness, as to render it productive of nothing but rushes and other aquatic plants, and if a pit or ditch be made in lands under these circumstances, it quickly fills with water to the same level as that in the watercourse. This effect is, however, more liable to be produced, as well as more complete, where the current of the water is slow and its surface nearly equal with that of the land, than where its descent is rapid. Under such circumstances, while the river or brook remains at the ordinary height, no advantage can be gained, whatever number of drains be formed, or in whatever direction they may be made. The chief or only means of removing the wetness of land proceeding from this cause is, that of enlarging and sinking the bed of the stream, where it can be effected at a reasonable expense: where there is only one stream, and it is very winding or serpentine in its course, much may however be effected by cutting through the different points of land, and rendering the course more straight, and thereby less liable to obstruct the passage of the water. But in cases where there are more than one, that should always be made the channel of conveyance for draining the neighbouring land, which is the lowest in respect to situation, and the most open and straight in its course. It may likewise, in particular instances, be advantageous to stop up and divert the waters of the others into such main channels, as by such means alone they may often be rendered deeper, and more free from obstruction: the materials removed from them may serve to embank and raise up the sides to a greater height, as while the water can rise higher than the outlets of the drains, and flow backwards into them, it must render the land as wet as it was before they were formed, and the expense of cutting them to be thrown away.

1242 *The collected rain-water becoming stagnant* on a retentive body of clay or some other impervious material, as it can have no outlet of the natural kind, causes such lands to become soft and spongy thus forming bogs of a very confined kind. As such bogs are often situated very greatly below the ground that surrounds them, the opening of a main drain, or conductor, to convey off the water collected by smaller drains, would be attended, in many instances, with an expense greater than could be compensated by the land after it had been drained. The thickness of the impervious stratum that retains and keeps up the water in such cases is often so great, that though the stratum below be of a porous and open nature, such as sand, rock or gravel, the water cannot of itself penetrate or find a passage from the one into the other; consequently, by its continued stagnation above, all the different coarse vegetable productions that have for a great length of time been produced on its surface, and probably the upper part of the soil itself, are formed into a mass or body of peat earth, equal in softness to that of any bog originating from water confined below, and less productive, and which is only capable of sustaining the weight of cattle in very dry seasons, when the wind and sun have exhiled and dried up a great part of its surface moisture, but even then it is incapable of admitting the plough upon it.

1243 *As these kinds of bogs differ materially in their origin from those which have been already noticed, their drainage must of course be accomplished in a different way.* The following method of proceeding is recommended as perhaps the most expensive. — In the middle, or most depending part of the ground, the first drain (fig. 50th a) may be cut, into which all the others should be made to lead; the number and direction of which must be regulated by the extent of the bog. They should be cut through the peat, or moist spongy upper soil, to the surface of the clay, or other retentive stratum of materials, which must then be perforated or bored through in order to let the water down into the pervious stratum below, by which it may be absorbed and taken up. The same effect might be produced by plugging one lower well, or pit, in the middle or lowest part of the bog, through into the porous stratum below, and connecting the other drains with it, as by such a method the trouble and expense of boring along the drains would

be equal. In these cases, when drains are made, they should always be cut as narrow as it is possible to

make them, and, after the holes have been formed in them by turning, filled up with loose stones to within about a foot and a half of the surface, which open may be made up by a portion of the earth that had been taken out, putting in turf with the grass side to the stones before the earth is thrown in. By this means the water and perpendicular moisture of the peat, or upper soil, may be taken away by the drains, and pass off through the holes that have been formed in their bottoms. But where pits are employed, these should only be filled with small stones to the level of the bottom of the drains, the filling being performed as soon as possible after they are formed. (*Agriculture's Treatise on Draining*, p. 84.) Where there is a shaly stratum below after taking it out, the faults contained in it may be made use of in this way with much advantage and where the drains can be carried into quarries, where the stone is much floured so that more will be necessary. Where land of this sort is afterwards to be ploughed, great attention should be given to the forming of the ridges and giving them a regular descent towards the main drain, which will contribute greatly to the assistance of the others in conveying off heavy hills of rain-water when they occur.

689. But a necessary precaution previously to any attempt to drain lands of this kind is in the way that has been described, is to ascertain whether the porous stratum under the clay be dry, and capable of receiving the water when let down into it, or already so loaded with moisture that, as, instead of receiving more from above, to force up a large quantity to the surface and thus increase the evil it was intended to remove. This may be the case in many instances, and the stratum contain water which affords no appearance of wetness on the surface, at the place on account of the compact body of clay that is placed over it, but which, from its being connected with some spring that is higher may flow up when an opening or passage is given it, either by means of a pit or the sump. In this way a greater quantity of water might be brought to the surface, which from its being confined by the surrounding banks, would render the ground much more wet than before, and in particular situations produce very great degrees of wetness. When the surrounding high ground declines lower than the bog though it may be at a considerable distance by the aid of the level, and the appearance of the surface, the nature of the stratum underneath may in some degree be ascertained and, notwithstanding it may already contain water a drain may be formed into it to carry off that water and what may likewise be let down into it from the retentive stratum that lies above it. It must be confessed, however, that cases where surface water can be let down through a retentive stratum to a porous one that will actually carry it off are very rare. When these occur it is chiefly in limestone or coal districts, where the surface is hilly or rugged (*Ag* 630.), and more calculated for

the purposes of the mineralogist than those of the agriculturist.

### SECT. III. Draining Hilly Lands.

4845. *Draining hilly lands* is not in general attended with great expense, as the drains need seldom be covered or filled up, only in such places as may be sufficient for passages for the animals to cross by and though, where the depth of the trench does not come to the water confined below, it may be necessary to perforate lower; there need not be any fear that the holes will fill up, even where the drain is left open as the impetuosity of the water itself will remove any sand or mud that may fall into them, where much flood or surface water does not get in. Small openings may however, be made along the upper side of the trench, in order the more effectually to secure them against any obstructions, and in these the perforations may be made, leaving the mouth of the holes about six inches higher than the bottom of the drain, which will be without the reach of the water that may be collected during the time of heavy rains.

690. One of the greatest improvements of the hilly sheep-pastures of Holland has been effected by drainage, while the expense is comparatively small. The depth and width of the small ones are only those of the spade. They are usually carried across the face of the hills in a slightly unlevel direction, so as to avoid the injury of too rapid a descent after heavy rains; and these small cuts open into a few larger, formed with due regard to the same principle; the whole at last, for an extent of several hundred acres, being let into one still larger, which discharges itself into the nearest rivulet. Improvements of this kind are, perhaps, of greater benefit to the individual proprietors of land who undertake them than any other.

4847 The sides or declivities of many hills, from the irregularity of the disposition of the strata that compose them, are often covered with alternate portions or patches of wet and dry ground. By the general appearance of the surface and the vegetable products that are grown upon it, the nature and direction of the internal strata may frequently be ascertained with so much certainty as to determine the line or direction of a drain without the necessity of examining below the surface of the land. As the case or difficulty

of draining such grounds depends solely on the position of the different strata of which the hill or elevation may be formed, and upon the erect or slanting direction of the rock, or other retentive body in which the water is contained, where the rock has a slanting or horizontal inclination, the whole of the different springs or outlets, that show themselves on the surface, may originate from or be connected with the same collection or body of water, and may be all drained and dried up by cutting off or letting out, the main body of water, by which they are supplied, at the inferior part of the reservoir or that part where the water would of its own accord readily run off if it were not confined beneath an impervious covering of clay or some other material.

4248. But in cases where the rock lies in an erect or perpendicular form, and contains only partial collections of water, in some of the more open cracks or fissures of the stone, which discharge themselves at various openings or outlets that have not the least connection with each other, it would be an idle and fruitless endeavour to attempt the cutting of them off by means of one drain (fig 631 a), or by boring into any one of them in

particular, without cutting a drain into each (a, b, c). In this case it is more advisable to make the main drain wholly in the clay with small cuts made up to each outlet, than along the place where the springs burst out as in that line of direction it would be

too much in the rock and consequently be extremely difficult to cut, on account of the nature and disposition of the stone. When the water passing out on the line of the springs can be found by the auger in the main drain, at the point of junction, it will be the more completely cut off but where this is not practicable, the depth of the small cuts may reduce it to such a level as will prevent its flowing over and injuring the surface of the land below it.

4249. In such hills as are constituted of alternate strata of rock sand, and clay, the surface of the last may frequently be wet and swamp, while that of the sand is dry, and capable of producing good crops of grass. In all such cases, in order to drain the land completely, as many cuts will be necessary as there may happen to be divisions of wet and dry soil. The summit, or most elevated part of such hills, being mostly formed of loose porous materials, the rain and other water descends through it till its passage becomes obstructed by some impervious bed or stratum, such as clay, when it is forced up to the surface, and runs or oozes over the obstructing stratum after having overflowed the upper clay surface, it is immediately absorbed and taken up by the succeeding porous one, and, sinking into it in the same way as before, passes out again at the lower side, rendering the surface of the next clayey bed prejudicially wet, as it had done that of the first. In this way the same spring may affect all the other strata of the same kind, from the highest part down the whole of the declivity and produce in the basin, or hollow at the bottom, a lake or bog, should there not happen to be a passage or opening to take away the water. In order effectually to drain hills of this kind, it will be most advisable to begin by forming a trench along the upper side of the uppermost rushy soil, by which means the highest spring may be cut off; but as the rain and other water that may come upon the next portion of porous soil may sink down through it to the lowest part, and produce another spring, a second cut must be made in that part, to prevent the water from affecting the surface of the succeeding clayey bed. Similar cuts must be formed so far down the declivity as the same springs continue in the same way to injure the land, and in some cases a sufficiency of water may probably be obtained to irrigate the land below, or for some other useful purpose.

#### SECT. IV. Methods of draining Mixed Soils.

4250. Where the soil is of a mixed and varied nature, but the most prevailing parts of the clayey kind, the business of draining is considerably more tedious and difficult than where the superficial and internal parts have greater regularity. In such lands, as the collections of water are completely separated by the intervening beds of clay, each becomes so much increased in the time of heavy rains, as to rise to the level of the surrounding surface, when the water, finding a free passage, as it would over the edges of a bowl, overflows and saturates the surface of that bed of clay, rendering it so wet and sour that its produce becomes annually more scanty, and the soil itself more sterile and unproductive.

4251. From the sand-beds (fig. 632 a, a, a) in such cases having no communication with each other, it must evidently require as many drains (b, b, b) as there are beds of this kind, in order fully to draw off the water from each of them. A drain or trench is therefore recommended to be cut from the nearest and lowest part of the field intended

to be drained (a), up to the highest and most distant sand-bank (c), in such a line of direction as, if possible, to pass through some of the intermediate sand-beds, and prevent the labour and expense of making longer cuts on the sides, which would otherwise be requisite.

4252. *When the different beds of sand and clay are of less extent, and lie together with greater regularity, they can be drained in a more easy manner with less cutting, and of course at less expense. Below the layers or beds of sand and clay that lie, in this manner, alternately together, and nearly parallel to each other, is generally a body of impervious clay, which keeps up the water contained in the sand, which sand being constantly full, the adjacent clay is thereby rendered moist, and in wet seasons the water runs or trickles over it. As in these cases, the principal under-stratum of clay is rarely more than four or five feet below the surface, it is advisable to cut a drain (fig. 633. a)*

to that depth through the middle of the field, if it have a descent from both sides, but if it decline all to one side, the drain must be made on that side (b) as the water will more readily discharge itself into it, and, unless the field be of great extent, and have more than one depression or hollow in it, one drain may be quite sufficient for the purpose, as by crossing the different beds that retain the water it must take it off from each.

4253. *A principal difficulty in draining ground of this nature and which renders it*

impracticable by one drain, is when the direction of the alternate layers, or beds of clay and sand, lies across the declivity of the land (fig. 634 a, a), so that one drain can be of no other service than that of conveying away the water after it has passed over the different strata, and would naturally stagnate in the lowest part of the field, if there were no other passage for it. Where the land has in this way, which is frequently the case, it will therefore be necessary besides the drain in the lowest part (b), to have others cut up from it in a slanting direction across the declivity (c, c), which, by crossing the different veins, or narrow strata of sand (d, d, d), may be capable of drawing the water from each of them.

4254. *In forming the drains in these cases, it is recommended that, after laying the bottom in the manner of a sough, or in the way of a triangle, it be filled some way up with small stones, tough sods with the green side downwards being placed upon them before the mould is filled in. But where stones cannot be readily procured, faggots may be employed, the under part of the drain being laid, or coupled, with stones, so as to form a channel for the conveyance of the water that may sink through the faggots, and for the purpose of rendering them more durable, as, where the water cannot get freely off, which is generally the case where there is not an open passage made of some solid material, it must, by its stagnation, soon destroy the faggots, and choke up the drain.*

4255. *The success of Spatterwode in Dorsetshire affords an interesting example of successful drainage of mixed soil and strata. It was begun in 1815, under the direction of Mr. Stephens, an excellent draining engineer, and author of a useful work on the subject (The Practical Drainer &c., Edin. 8vo. 1820), and eighteen miles and a half of drains, some parts of which were thirteen feet deep, but the greatest depth of which was from five to seven feet, had, in 1824, rendered between five and six hundred acres of land most valuable, which had been before of little value.*

4256. *The ground to be drained at Spatterwode "consisted of a soil of various depth, under which commonly lay a stratum of clay from two to three feet deep, then a thin bed of sandy or gravelly substance, of a foot deep, or more, containing water; after that another bed of clay of two or more feet deep; and lastly a bed of sand, gravel, or stony rock, containing the larger quantity of water." Upon reaching the*

who, by practice, is equally competent, this person always working at daily wages, to prevent him from having any interest in hurrying over this most important part of the operation."

4262. *The drains may be cut only "two feet wide, with the sides perfectly perpendicular, provided that, from the tenacity or hardness of the substances dug through, the sides will stand till the stones are put in. It is usual, however, to break the ground somewhat wider at the top, and so to give it a slight slope to the bottom. The work of cutting is always done by contract at so much per rood or yard, and several labourers generally join in making one drain, and arrange the work among themselves. The casting or cutting, it is scarcely necessary to observe, is always commenced by the workmen at the lower end, and worked upwards to the higher ground, and never downwards. They usually begin by working about two feet deep in the first instance, several roods in length, then going over the ground again, deepening it to four or five feet, and afterwards going over it the last time and finishing the bottom, by making it perfectly level and ready for the mason to build the conduit in the bottom. The bottom must, for this purpose, be completely two feet wide, though, when free-stone is employed, the width may be less."* (*Trans. Highl. Soc.*)

4263. *In building the drain, "the mason has an assistant, generally a female at the top, who hands him the stones he requires. He begins with small flat stones to build the wall on each side of the bottom of the drain nine inches broad, and six inches high, so as to leave six inches for the conduit in the middle. Thus he does roughly but in such a manner that the stones shall be laid solidly on one another. When the ground at the bottom is solid, either dry gravel, or clay or rock, the mason's foot, with his ordinary clog or shoe, standing in the centre is the measure of the width of the conduit. When the land is inclined to be wet and soft, a plank six inches broad is used for him to stand upon. When the bottom is a wet spongy clay or sand of the nature of a quicksand, or very soft, it is often necessary to flag the bottom of the conduit with very thin stones or slates."* (*Trans. Highl. Soc. vol. vii.*)

4264. *When a perfect quagmire has been met with, "which has happened chiefly in red clay, the faster the wet clay has been thrown out, the faster it has boiled up from below. In these cases, it has been found necessary to lay planks on the bottom of the drain, and build upon them. But this will very seldom be necessary where proper precautions are used. On first meeting with quagmires of this kind, attempts were made to dig them out for which purpose a strong wooden frame was made large enough for four men to work in with freedom, composed of different pieces, so that the workmen might add to the sides of the frame as they worked downwards. Notwithstanding the frame's being made very strong the pressure became so great, that the sides came together, and stopped the operation. The consequence was, that after great labour and active exertion in taking out large quantities of wet clay which thus continued to boil up (but the very taking out of which undermined the banks from beneath) the sides of the drain fell in masses, and made great gaps, which increased the longer the work was carried on. In these circumstances, it became necessary to use planks to build the conduit, and to fill in the stones as fast as possible, by employing a great number of persons at once. The weight of these superincumbent stones then kept the planks and conduit at their proper place, so much so that the worst of these parts never exhibited any symptom of imperfection, though made ten years ago. On all occasions afterwards, however, when any of these quagmires were found, the process of taking out the bottom of the drain was followed, yard by yard, by flagging the bottom, building the conduit, covering it, and filling the stones over it and in this way the quagmire was prevented, by the immediate pressure from above, from boiling up. It never failed to be seen that the longer these operations were delayed, the softer and more intractable the interior of the drain became. After building the side walls for a yard or two in length, the mason, according to circumstances, cleans out the conduit with a narrow hoe, and then covers it with such large broad stones as he can procure, from fifteen inches in length to two feet, being the utmost width of the drain itself. These are handed down carefully to him by his attendant; and, after he has laid three or four of them, he takes smaller flat stones, as the larger are always uneven at the edges, and covers every interstice; and afterwards, with similar stones, packs carefully the ends of the covers, before finishing any particular portion of the work so as to prevent them from shifting and still further to cover every hole through which any thing might be carried into the conduit, he has a rolled up whip of straw which he puts in the mouth of the conduit, which allows the water to pass out, but prevents mud and sand from getting in. His attendant then throws the remainder of the stones in promiscuously to the depth of two feet, or sometimes more, if the materials are plentiful, and particularly where there are two seams con-*

taining water; for in this case it is generally desirable to raise the stones above the level of the bottom of the upper *seam*, so as to convey away any water which may remain in it, to the conduit beneath (Fig 637 a, sand or gravel b, clay); and it was a circumstance very generally observed in the course of operations, that where the upper stratum containing water was only a few feet in depth or thickness, another open stratum was generally found a few feet deeper.

**4265 Stones.** When the stones to be used are only brought forward at the time of cutting the drain, the carts are often run back to the edge of it, and the stones, after the conduit is built, tumbled straight out of the cart into the drain but, in this case, it is necessary to take care that the sides of the drain be not injured by the cart-wheels or otherwise, lest the earth should fall into the drains, and so through the intervals of the stones. A part of the stones for filling were recommended by Mr Stephens to be broken like large road metal. Thus, however is very expensive, and was found by experience not to be necessary though usually large stones should be broken. When the stones are small that is, ten or twelve ounces, it is as well but no inconvenience has been found from the constant use of stones of a much larger and very unequal size. When a sufficient quantity of stones has been thrown in the mason levels them at the top, filling up the intervals of larger stones with smaller ones, so as to make the top of them level. If the sod which has been cut off the surface of the drain is sufficiently solid, it should be laid carefully by itself on the upper edge of the drain at the side of the stones. It should again be laid with its gravelly side undermost, on the top of the stones, as a covering to prevent the earth from getting down amongst them. If the *sods* are not sufficiently coherent or plentiful to cover the whole completely old coarse hay or straw or heath, may be used as a substitute. When all this is completely done, the earth is shovelled in upon the top, until the drain is full. It is then heaped up, somewhat after the manner of a grave, to allow for the earth's subsiding to the level of the surface. It is a circumstance deserving of notice, that, in digging the trial-pits, the earth taken out is in most cases insufficient to fill them again, if allowed to lie open for any time so that, in fact, contrary to what would be naturally inferred, the earth must become more compact by being removed.

**4266 Repairs.** When the drain is thus completed, it is still necessary and particularly when the land is under tillage, carefully to inspect it from time to time, and to see that no surface-water finds its way into it. If any hole is found, it ought to be immediately stopped up, as a channel of this kind will sometimes very speedily carry enough of mud into a conduit to choke it entirely and spoil the drain. Under draining, it will be kept in mind, will not supersede the necessity of surface-drains, where these are necessary to carry off water stagnant upon the ground. Besides the danger to drains by the flowing in of surface water there are other sources of injury which must be guarded against by a vigilant care. *Animals*, by burrowing in the earth, or finding their way from any course in the conduit, are sometimes apt to injure it, and cause the earth to crumble in, but a more frequent source of injury is from vegetable substances, as roots of trees, and particularly of the *sals*. As an instance of this, there happened, on this property to be an ash tree growing near a drain, the fibres of which took possession of the conduit, and so obstructed the passage of the water, as to produce a new swamp, in consequence of which it became necessary to lift the materials of the drain, and form it anew. It is often very difficult to eradicate certain plants, whose long and creeping roots get interwoven in the interstices of the conduit. The advance of these larger animals which enter the conduits for safety, or in pursuit of prey, may be prevented by an iron grating at the outlet. (*Trans. Hygl. Soc. vol. vi.*)

#### SECT V. Methods of draining Retentive Soils.

**\*4267** The mode of draining retentive soils is materially different from that which has been described above. Many tracts of level land are injured by the stagnation of a superabundant quantity of water in the upper parts of the surface materials, which does not rise up into them from any reservoir or springs below. The removal of the wetness in these cases may, for the most part, be effected without any very heavy expense. From the upper or surface soil, in such cases, being constituted of a loose porous stratum of materials, to the depth of from two to four or five feet, and having a stiff retentive body of clay underneath it, any water that may come upon the surface, from heavy rains, or other causes, readily filtrates and sinks down through it, until it reaches the obstruct-

ing body of clay; the consequence of which is, that the porous open soil above is so filled and saturated with water, as to be of little utility for producing crops of either grain or grass. Land thus situated is frequently said by farmers to be wet-bottomed. In order to remove this kind of wetness, it seldom requires more than a few drains, made according to the situation and extent of the field, of such a depth as to pass a few inches into the clay, between which and the under surface of the porous earth above there will obviously be the greatest stagnation, and consequently the largest collection of water, especially where it does not become much visible on the surface. In these cases there is no necessity for having recourse to the boring instrument, as there is no water to be discharged from below.

4363. When the field to be drained has only a slight declination, or slope, from the sides towards the middle, one drain cut through the porous superficial materials into the clay, in the lowest part of the ground (fig. 638. a), may be sufficient to bring off the whole of the water detained in the porous soil. This effect may likewise be greatly promoted, by laying out and forming the ridges so as to accord with the direction of the land, and by the use of the plough or spade in removing obstructions, and deepening the furrows. In such situations, where the drain has been formed

in this manner the water will flow into it through the porous surface materials, as well as if a number of small trenches were cut from it to each side, as is the practice in Essex and some other parts of the country but which is often an unnecessary labour and expense. The drain made in the hollow may frequently serve as a division of the field (a), in which case it may be open,

but in other circumstances it may be more proper to have it covered.

4369. Where a field of this description has more than one hollow in its surface (fig. 639 a, b), it will obviously be requisite to have more than one main drain but when it is nearly level, or only inclines slightly to one side, a trench or drain along the lowest part, and

the ridges and furrows formed accordingly, may be sufficient for effecting its drainage. There may, however, be cases, as where a field is large and very flat, in which some side-cuts from the principal drain may be necessary, which must be made a little into the clay and as narrow as they can be wrought, and then filled up with stones or other suitable materials.

4370. What is called the Kent method of draining in ploughed springy lands, where the surface soil is tenacious, is described by Kent, and consists in substituting small under-drains (fig. 640. a) for open furrows or in some cases having a small under-drain beneath

(b) every other or every third furrow. These drains lead to side or fence ditches (c), where they discharge themselves.

4371. Where the clay constitutes the surface, and the porous body is underneath, the injurious stagnant water cannot possibly get off, without the assistance of drains formed for the purpose. Soils of this nature are drained with difficulty, and require a much greater number of trenches or cuts than those of any other kind, as they must be marked out and disposed in such a way as to collect and convey the water every where from the surface, because it can only flow itself off into them from above, being prevented from

sinking is through the clay as in soils of a contrary kind. Where there happen to be hollows or irregularities in the surface of the land, water may often be observed to continue standing in them, at a distance of but a few feet from the drains. In draining such lands, it will always be necessary in the first place, to make a large or conducting drain at the lowest part, or the end of the field, for the purpose of receiving and conveying away the water collected by the smaller collateral cuts which it may be necessary to make on each side of it. Where it suits for the purpose of dividing the land, the principal drain may be better open than covered, as by that means the mouths or outlets of the different small drains that come into it may be conveniently examined, and cleared out when necessary.

4372. *The construction of the ridges in such soils, so that they may accord with the declivity, is a matter which must be carefully kept in view.* They should in all such cases have a degree of elevation or roundness in the middle, sufficient to afford the water a ready fall into the furrows, which likewise should have such a depth and fall as may take it quickly into the drains. *The ridges, besides being well laid up, should have small open drains formed in a slanting direction across them, in such a manner as to form communications with one another and with the furrows by which means they are made to perform the office of drains the water coming upon the ridges being thus readily conveyed into the furrows, along which it proceeds till impeded in its course by the rising of the ground or other cause it then passes through the open cross-drains into others where the descent is greater and is ultimately conveyed off into the ditch, or other passage at the bottom of the enclosure.* The elevation of the ridges should probably too, be made greater for the winter than the summer crops, as there must be much more injurious moisture at the former than the latter season. This may be easily accomplished at the time of ploughing the land. Some useful observations on this description of drainage will be found in Marshall's work on *Landed Property*, and in Dr Anderson's *Treatise on Draining*.

#### SECT VI *Methods of draining Mines, Quarries, Pits, Ponds, and Lakes.*

4273. *Where pits, mines, or quarries, happen to be formed at the bottom of declivities, and are inconvenient or wholly obstructed, either in the digging or working by the water contained in them, it may be possible, in many cases, to prevent its coming into such mines or pits, by cutting or boring into the lower parts of the porous strata (fig 641 a).* In order to accomplish this object, it will be necessary to ascertain if any

641

porous stratum presents itself higher up the elevation than the place where the mine or pit is formed, that may conduct the water it contains to the porous body below it as by cutting into such stratum, where discovered, much of the water may be drawn off and prevented from passing down. But notwithstanding the water from above may be cut off in this way, a quantity sufficient to inconvenience the working of the mine or pit may still filtrate from the sides of the porous bed, even though it may incline in the direction of the lower ground. When this is the case, it may, however be readily taken away at some place in the bed. To accomplish this, and thereby obviate the effects of the water the termination of the porous stratum (fig 641 a) below the pit must be ascertained and where there is any mark of a natural outlet at the place, a large drain should be formed, in order to permit the water to flow off with more expedition. Where, however, there is a thick bed of some impervious substance, such as clay, placed upon

the termination of the porous material, the drain need only be cut a little way into that, as by boring through the rest a sufficient passage may be given to discharge the water. In this way, the draining of such grounds as lie above or near to mines or pits may be of great advantage.

4274. *When a quarry or other pit to be dried (fig. 642 a) is situated above a porous*

*stratum, whether of rock or gravel, it may sometimes be drained by boring into the latter (b). In this way different chalk pits and lime quarries have been*

drained in Kent and Hertfordshire. (See the Reports of these Counties.) In marl-pits also, which, from the nature of their situation, mostly require much cutting through some part of their sides, in order to remove the water that prevents their being wrought, the mode of letting the water down by means of pits dug through the upholding stratum below the bed of marl into the porous materials underneath, might be economically practised. In such cases, the number of the pits must be proportioned to the space occupied by the marl and when they are required to be of such depths as to be liable to give way, they should be built up, or nearly filled with loose stones, so as to admit the water to pass off such lateral drains as are necessary communicating with them. In some situations of the pits, as where the bank slopes lower on the contrary side than the level of the water an easier mode may be practised such as by forming a drain in it, and then perforating with a horizontal boring-instrument into the terminating part of the stratum that holds the water thereby removing and keeping it below the level of the marl. In addition to these, in some cases, as where the water of such pits proceeds from springs in the high grounds above them, it may be useful to intercept and convey it away before it reaches the marl-pits.

4275. *The drainage or drying up of lakes or ponds comes occasionally within the practice of the drainer especially in countries with an irregular surface. There are, perhaps, few natural lakes indeed, the surface of the water of which might not be very considerably lowered, by deepening their natural outlets, the consequence of which would be, in many cases, a very considerable accession of generally rich land round their margins, a better drainage for the surrounding country and an improved climate. Much, it is said, might be done in this way in Ireland but there can be no doubt that in every country in the world a great deal may be done. In flat countries nearly on a level with the sea, like Holland and parts of the counties of Cambridge and Huntingdon, the water will in general require to be raised by machinery but in by far the greater number of cases, deepening the natural outlet will be found amply sufficient.*

4276. *Bar Loch, in the county of Renfrew was reduced in size by drainage and embanking, in 1814, at an expense of nearly 10,000*l.* which has since returned 13 per cent. per annum. 250 acres have been laid dry upwards of 200 of which have been since under crop. A very interesting account of this drainage will be found in the Highland Society's Transactions, vol. vii. p. 375.*

4277. *Steam-engines have lately been employed both in Cambridgeshire and I. p. 375, as substitutes for the very uncertain power of wind, to raise the water from the low lands, and deliver it into the drains and rivers by means of scoop wheels working like a grinding-stone in its trough. Wheat and other corns have thus been sown on lands never before ploughed. The improvement indeed is one of the greatest that has taken place in many countries, since they were first attempted to be drained and embanked. (Mech. Mag. vol. v. p. 173. and Gard. Mag. vol. iv and v.)*

#### SECT. VII. Formation of Drains, and Materials used in filling them.

4278. *Drains should be formed with as much truth and exactness as possible; such labourers as are not dexterous in using their tools seldom make them well. The most general method of performing this sort of work is by admeasurement, at so much a rod, or a score of rods, which necessarily induces the workmen to do as much as they possibly can: they should, therefore, be frequently inspected, to see that they keep to the proper and required depth, that the earth taken out be laid in such a manner as not to fall down again into the drains in time of filling them, and that the surface should be kept on one side free from the clayey or other material of the inferior stratum.*

4279. *When there is any declivity in the ground, drains should be made in a slanting direction across it, instead of the old method of conducting them according to the nature or inclination of the slope. By attending to the former mode of cutting the drains, the wetness is not only more effectually removed, but, by allowing the water to pass away in an easy current, they are rendered less liable to be choked, or, as it is frequently termed, blown up, by which artificial coverings of water are sometimes formed in such places. But where grounds are either quite or nearly level, it has long been a general practice to cut the drains at the different distances of about sixteen, twenty four and*

thirty-two feet from each other, across the fields from the different ditches, according to the circumstances of the lands or indeed, where the drains, either from some slight unevenness of the surface, or other causes, can only be made to flow at one end, to avoid cutting them further on one side than where the ditch is capable of taking away the wetness. In cases where the declivities of a piece of ground are various, and have different inclinations, the drainer should constantly attend to them, and direct the lines of his drains in such a manner as that they may cross the higher sides of the different declivities in a slanting direction.

4280. *The depth of drains* must depend upon the nature of the soils, the positions of the land, and a great variety of other more trifling circumstances. It was formerly the custom to make them three or four feet in depth but by modern drainers the most general depth is two and a half to three feet. As the main drains have more water to convey away, and are generally of greater length than the lateral ones, they should always be cut somewhat deeper and where the materials of the soils are porous, the deeper they are cut, the more extensively they act in lowering the wetness of the land when, however the operator reaches any material through which the moisture cannot pass, it will be useless to dig the trench to a greater depth. If it be clay by going a few inches into it, a more safe passage for the moisture may however be secured. It must notwithstanding be invariably attended to, that the depth of the drains be such as that the treading of heavy cattle may not displace, or in any way injure, the materials employed in constructing or filling them. It may be noticed too, where the horses in ploughing tread in the bottom of the furrow at the depth of four inches or more below the surface, that, if eight or ten be allowed for the materials with which the drains are filled, when the depth of the trenches does not exceed twenty-four inches, there will only be nine or ten inches of earth for the support of the horses when ploughing. Where the earth has been stirred, such a depth must undoubtedly be too little and this in some measure proves that drains of such a depth are not sufficient. By cutting them down to the depth of two feet and a half in the stiffer soils, they will seldom be penetrated to, or have too great a depth and in the pervious ones a still greater depth is highly useful and constantly to be practised.

4281. *Cutting the drains as narrow as possible*, which has of late been much practised, is of importance, as it causes a considerable saving of the matters employed in filling them up, whether wood or straw but in cases where bricks or stones are used, this cannot be so much attended to however a greater width than about a foot is seldom necessary provided the stones be coupled at the bottom or thrown in in a mixed way nor more than sixteen inches where laid in the manner of a sough or channel. But of whatever depth the materials may be, the earth or mould by which they are covered up should not be less in depth than a foot in arable lands it should be more.

4282. *The different sorts of drains in use* may be classed in two divisions drains of conveyance (fig 643 a, b,) alone, and drains of conveyance and collection jointly (fig

644 c, d.) In the former all that is necessary is a channel or passage for the water of sufficient dimensions, which may be formed by pipes of different kinds, arched or barrel drains (b), and box or walled drains (a). The construction of the latter requires not only an opening for conveying the water, but a superincumbent or surrounding stratum (e, f) of sufficient porosity to permit and induce all latent water to find its way to the channel of conveyance. The most complete drain of conveyance is a large pipe of metal, masonry, or brick-work and the most complete collecting drain, one formed of a channel built on the sides, and covered with flat stones, with a superstratum of round stones or splinters, diminishing to the size of gravel as they rise to the surface, and there covered with the common soil. As the best constructions, however are not always practicable, the following are a few of the leading sorts adopted for different situations.

4283. *For drains of conveyance*, there are the walled or box drain (fig 643 a) the barrel drain (b), the walled or the triangular drain (c), and arched drains (fig 644).

4284. *Drains of collection* are formed of stone, brick, gravel, splinters, wood, spray straw turf, and earth-stones.

4285. *The barrel and rubble drain* (fig 644 c) has been already described as a drain of conveyance and col-

bottom. The common rubble drain is formed of rough land stones of any sort, broken so as not to exceed two or three inches in diameter. No good drainer uses stones six or eight inches in diameter in any part of a rubble drain, least of all at the bottom. The point kept in view is to use such small stones at the bottom so as to allow the water a great many channels, so that, if a few should become impermeable, there should be many others remaining. The nearer the bottom of a drain of this kind approaches to the character of a natural bed of gravel, the more certain will be the free passage of the water. Gravel or shales should be laid on the top of the stones, on these a thin layer of straw or haulm of any kind, and the remainder filled up with the surface soil.

646. The brick drain is formed in a great variety of ways, either with common bricks and laid in imitation of the boxed or rubble, or rubble drain or with bricks made on purpose, of which there is great variety (fig. 646, a to e). Draining tiles, to be used with effect as collecting drains, should generally be covered a foot in depth or more with stones or gravel. But if the land to be drained be in grass, laying the sod over the tile is sufficient. If the land be not in grass, and be loose in texture, a little straw may be profitably laid over the tile, to prevent the soil from running in. The pantile (d) is the best for general purposes, but ought not to have holes at top but sometimes such holes are made in very old soils, plain tiles are wanted to place the draining tiles on in other soils, old broken pieces of plain tiles are sufficient for the ends to rest on. Sometimes, even at depths of six feet, these tiles, though of six inches in the clear will be entirely blocked up by the fibrous roots of trees, especially of the black poplar. A variety of this tile, of a more ample capacity has lately been brought into use in Lincolnshire (fig. 647). The best draining tiles in England are manufactured at the Staffordshire potteries and Peake, of Tunstall, may be assumed as eminent in this line. (Gard. Mag. vol. v and vi.)

647. On the Margate of Stafford's estate, "an allowance of draining tiles is made wherever the exertions of the tenants seem to merit such a reward. In order to secure the drains being properly filled up with stones above the tiles, the tenant is obliged to drive a sufficient quantity of stones or cinders from the furnace, and lay them on the ground, previously to an order being made for the delivery of the tiles. Without attending to this important circumstance much draining would be thrown away. The park at Trentham is a complete illustration of this remark. The draining of this spot was conducted under the direction of Elkington. The wetness with which these lands are affected does not arise from any ill of springs harrying out from the upper grounds, to which that gentleman's system of deep drains could be applied, but is occasioned almost entirely by the retentive nature of the subsoil, and by its being interstratified with small beams of sand, which he detached and unconnected with each other in the bed of clay. To cure this species of wetness, a number of small drains, well filled up with one cut in each of these beds of sand, is necessary. In pursuance of this plan a great part of the park at Trentham has been lately drained over again, by making a number of small shallow drains, about fifteen feet asunder in some instances above the old ones, taking particular care to fill them up as well as possible, and not to permit any clay to be laid over the stones. This has proved effectual. (Lock.)

648. The gravel or cinder drain is seldom made deep, though if the materials be large, they may be made of any size. In general they are used in grass lands. The section of the drain being an acute-angled triangle, and the materials being filled in, the smallest uppermost, nearly to the ground's surface.

649. The wood drain is of various kinds. A very sufficient and durable construction consists of poles or young fir-trees stripped of their branches and laid in the bottom of the drain in lengthways. They are then covered with the branches and spray. Another form is that of filling the drain with faggot-wood with some straw over. A variety of this mode (fig. 649) is formed by first setting in cross stakes to prevent the faggots from sinking, but they are of no great use and often occasion such drains to fail sooner than common faggot drains, by the greater vacuity they leave after the wood is rotten. In some varieties of this drain the brushwood is first laid down alongside the drain and formed by willow or other tree into an endless cable of ten or twelve inches in diameter, and then rolled in, which is said to form an excellent drain with the least quantity of materials, and to last a longer time than any of the modes above mentioned. Some cut the brushwood into lengths of three or four feet, and place them in a sloping direction with the root end of the branch in the bottom of the drain others throw in the branches at random, with little preparation, and cover them with spray straw or rushes, and finally the surface soil.

650. The spray drain is generally like the gravel drain, of small size, and formed like it, with an acute-angled bottom. In general the spray is tied firmly up though in some cases it is previously formed into a cable, as in the brush-wood drain. Drains of this sort are much in use in grass lands, and when the spray of larch wood, hoth, or ling can be got, they are of great durability.

650. It may be observed that the straw, being of one uniform substance, will rot and decay leaving a clear pipe through the land in every drain. The passage of the water into these drains

may be much facilitated by a due attention to filling them with the most friable and porous parts of the surface the field may afford.

650. *The easy drain* (figs. 650 and 651.), may be made of any convenient depth, but it must be at least the breadth of a turf at bottom. The drain being dug out as if it were to be filled with stones or any ordinary material, the operator next, with a spade three inches wide, digs a narrow channel along its centre (a), clearing it out with the draining scoop and over this the turves (b) are laid without any other preparation, or any thing put over them but the earth that was excavated. This is found to be a very cheap, and considering the materials, a surprisingly durable method of draining. Surviving, in pasture-fields especially, all the purposes that the farmer can expect to derive from drains constructed with more labour, and at a much greater expense. They are said to last frequently twenty years and upwards, but the period which it can be supposed they will continue to prove effectual must depend on the nature of the soil and the current of water.

652. *The wedge or triangular sod drain* (fig. 652) is thus made. — When the line of drain is marked out, a sod is cut in the form of a wedge the grass side being the narrowest, and the sods being from twelve to eighteen inches in length.

The drain is then cut to the depth required, but is contracted to a very narrow bottom. The sods are then set in with the grass side downwards, and pressed as far as they will go. As the figure of the drain does not suffer them to go to the bottom a cavity is left which serves as a watercourse, and the space above is filled with the earth thrown out. The work is performed by means of three spades of different sizes. The first may be a common spade of moderate breadth, with which the surface clay may be taken off to the depth of eight or ten inches, or not quite so much if the clay be very strong. The breadth of the drain, at top, may be from a foot to fifteen inches, but it never should be less than a foot, as it is an advantage that the sides should have a considerable slope, and the two sides should slope as equally as possible. Another workman follows the first, with a spade six inches broad at the top, and becoming narrower towards the point, where it should not exceed four inches. (fig. 653.a.) The length of the plate of this second spade should be fourteen inches, and with it a foot or four teen inches in depth can easily be gained. A third workman, and he should be the most expert, succeeds the second, and his spade should be four inches broad at top, only two inches broad at the point, and fourteen or fifteen inches in length (b). With this spade a good workman can take out at least fifteen inches of clay. A set of hoe or scarp, made of a plate of iron, formed nearly into the shape of a half cylinder of two inches diameter, and a foot or fourteen inches long, and fastened, at an acute angle of perhaps 70° to a long wooden handle (c) is now employed to scrape out the bottom of the drain and remove any small pieces of clay that may have fallen into it. The grassy side of the turf being turned undermost they are put down into the drain, the workman standing upon them after they are put in, and pressing them down with his whole weight till they are firmly wedged between the sloping sides of the drain. The ends of the turfs being cut somewhat obliquely they overlap each other a little, and by this means, although there is sufficient opening for the surface water to get down nothing else can. The open space, below the turfs, ought to be six or six inches in depth three inches wide at top, and an inch and a half or two inches at bottom. (Trans. High Soc. vol. vi. p. 671.)

654. *The hollow furrow drain* is only used in sheep-pastures. Wherever the water is apt to stagnate a deep furrow is turned up with a stout plough (fig. 654.a.)

After this, a man with a spade pares off the loose soil from the inverted sod, and casts it over the field, or casts it into hollow places. The sod, thus pared, and brought to the thickness of about three inches, is restored to its original situation, with the grassy side uppermost, as if no furrow had been made (b). A pipe or opening two or three inches deep is thus formed beneath it, in the bottom of the furrow sufficient to discharge a considerable quantity of surface water which readily sinks into it. These furrows, indeed, are easily choked up by any pressure, or by the growth of the roots of the grass, but they are also easily restored, and no surface is lost by means of them.

655. *The earth drain*, called also *the clay pipe drain*, is better calculated for the purpose of an aqueduct, or conveyance of water than for drying the soil. A drain is dug to the necessary depth narrow at bottom in the one end, and five at the other having a ring fastened in the thickest end. After drawing a little sand upon the upper side of the tree the clay or toughest part of the contents of the trench is first thrown in upon it, and then the remainder, which is trod firmly down. By means of the ring and a rope through it, the tree is drawn out to within a foot or two of the small or hinder end, and the same operation repeated. A gentleman who has tried this experiment says, this clay pipe has conducted a small rill of water a considerable way under ground for more than twenty years, without any sign of failing.

655. *Pipe drains of turf* are sometimes formed where the surface soil is a strong clay as it is only turves from such a surface that are sufficiently durable. A semicylindrical spade (Fig. 655, a) is used to dig the turves, the ground plan of which (b) presents a series of semicircles or half pipes. The drain (c) being dug out to the proper depth, one turf is laid in the bottom (d), and another being placed over it (e), completes the pipe. The same sort of pipe drain has been formed out of solid beds of clay and has served for a time to convey water. As collecting drains, of course they can be of little or no use. Hamsey an ingenious farmer in Wiltshire, adopted this mode for the purpose of conveying water through runn ag sand, in which only a pipe drain will last for a moderate time. After a number of years the clay curves were found effective in conveying away the water and preventing the running away of the sandy sides of the drain.

of ten inches (c) and it is immediately removed with narrow spades, and larger and smaller draining

656. *Pearson's method of pipe-draining* will be found described at length in the *Transactions of the Society of Arts* vol. xiv. for 1839. The ground is first opened by a plough, with what is called a horn share (a) a furrow nine or ten inches deep by ten inches is taken out. The horns are then removed, the coulter (b) added and eight horses attached. This cuts the soil to an additional depth

656

657. *Second pair of coulter cuts the soil to the depth required, which is also taken out by the scoops.* The total depth is now about twenty-six inches the width at top ten inches, and at bottom about one inch. A slide (Fig. 657, a) is then dropped to the bottom of the drain

657

commencing at its lowest level, so as to work up hill. A windlass (b) is next placed at the full length of the rope which is attached to the slide. Clay is next rammed firmly down on the slide with a heavy rammer to the depth of three or four inches, and the slide is next pulled forward, leaving a cylindrical drain of three or four inches in diameter according to the diameter of the slide. (*Trans Soc Arts* vol. xiv. p. 30.)

658. *A mode of turf-draining in use in Cheshire* is as follows. — The surface of the ground where the drain is intended to be cut, is marked out in parallelograms about the size of bricks on one side (Fig. 658, a), and that opposite is left of the width of a common sod, i. e. nine inches wide. These sods are taken out at a spade's depth, and laid carefully by the side of the drain for covers. The sods (c), resembling bricks in their size and shape, are then dug, and laid carefully on the same side as the sods intended for covers. The drain is then sunk to its proper depth, and the stuff taken out is thrown to the other side. The bottom is levelled with proper draught for the water, and set with the sods like bricks (a), two in height on each side (c) these are covered with the larger sods set obliquely (b), the grass side of each sod being turned downwards. (*Agr. Rep. of Cheshire* §14.)

659. *The wheel drain (Fig. 659)* is formed by the draining plough of that name already described (2643.) with the manner of using it. It is chiefly useful in pasture-lands, and especially in such as have some declivity, or are formed into ridges.

660. *The wheel drain* is a very ingenious invention described in *The Agricultural Reports of the County of Essex*. It consists of a draining-wheel of cast-iron, that weighs about 4 cwt. It is four feet in diameter; the cutting-edge or extremity of the circumference of the wheel is half an inch thick and increases in

thickness towards the centre. At fifteen inches deep it will cut a drain half an inch wide at the bottom, and four inches wide at the top. The wheel is so placed in a furrow that it may be loaded at pleasure, and made to operate to a greater or less depth, according to the resistance made by the ground. It is used in winter when the soil is soft, and the wheel tracks are either immediately filled with straw ropes, and lightly covered over with earth, or they are left to crack wider and deeper till the ensuing summer, after which the fissures are filled with ropes of straw or of twisted twigs, and lightly covered with the most porous earth that is at hand. Thus, upon grass or ley lands, hollow drains, which answer extremely well, are formed at a trifling expense. It is said that twelve acres may be fully gone over with this draining-wheel in one day so as to make cuts at all necessary distances.

4301. *Surface-gutters made by cart wheels* have been used by Middleton on meadows in Surrey. To the fell of a common cart-wheel (fig 660 a) is added a piece of wool, the section of which is a truncated triangle b, and on this is fixed a piece of iron competent, the triangle c. The cart is loaded and driven so that the prepared wheel may run in the furrow, or if there are no furrows, both wheels may be prepared, and the loaded cart drawn by two horses may be led over the whole field, forming parallel gutters four or five feet distant. The advantage of this mode of surface draining is that the herbage is only pressed down not destroyed, and rises up again in spring. The operation, for that reason requires to be renewed every winter. It certainly seems a barbarous mode but it may have answered better than one who has not seen it practised might be led to imagine.

4302. *In forming small drains chiefly for retentive soils* the common plough has been used in many places, and with some advantage. The method practised by Young as described in *The Annals of Agriculture* is this:—When he has marked the drains in a field usually a rod asunder he draws two furrows with a common plough leaving a baulk between them about fifteen inches wide then with a strong double breasted plough made on purpose, he splits that baulk and leaves a clean furrow fourteen or fifteen inches below the surface. But where the depth of soil requires it by a second ploughing he sinks it to eighteen or twenty inches it is then ready for the land ditching spade with which he digs, fifteen inches deep, a drain as narrow as possible. But the method followed by some farmers who do not possess ploughs made on purpose for the work, is this:—With their common plough, drawn by four or five horses, and usually stirring about four or five inches deep they turn a double furrow throwing the earth on each side, and leaving a baulk in the middle. This baulk they raise by a second bout in the same manner then they go in the open furrow twice, with their common double breast plough getting what depth they can. After this they shovel out all the loose mould and inequalities to the breadth of about a foot, and thus having gained a clear open furrow the depth varying according to the soil and ploughs but usually about eight or nine inches, they dig one spit with a drain spade sixteen inches deep 1) to gaining in the whole twenty four or twenty six inches. But as this depth is seldom sufficient when necessary they throw out another or even two other spits which makes the whole depth from thirty to forty inches.

4303. *The best season for marking out and forming drains* is the spring or beginning of summer because then the land springs, being still in vigour are more easily discovered and traced than at a later period. When the ground is soft on the surface it is a useful precaution, after the line is indicated, to cart on the materials for filling before digging the drain as the weight of the carriages and horses is apt to press in the sides. In the case of straw turf, or earth drains where the ground is of a firm texture, this precaution does not apply. In filling drains, the earth should always be raised somewhat above the general surface, to make allowance for sinking.

4304. *The duration of drains* must necessarily depend on the nature of the materials with which they are filled, and in some measure on the quality of the soil, as certain species of land have the power of preserving wood or other perishable materials much longer than others. Stones last till accidental causes impede the flowing of the water, and may last for ever. Wood perishes in certain periods, but it does not follow that the drains should stop if the earth arches, the water will necessarily continue to flow, which is found to be the case when wood, straw and stubble are rotten and gone. Drains that have been filled with bushes and straw, both which were rotten, have been observed to run well forty years after making.

4305. *The expense of drains* will of course vary with the soil, depth, price of labour, &c. and these circumstances are so different in different districts, and even in different parishes, that it accounts for the various reports of writers on the subject. Those farmers who are most solicitous to have the work well performed, contract with men only for digging and leaving clean, in order that the filling may be done by men paid by the day,

as a greater security that it should be executed with all possible care. Whatever may be the expenses and trouble incurred in draining, it may be safely asserted that, if the work is judiciously contrived and properly executed, no kind of outlay will prove so beneficial to the cultivator.

4306. The enemies of drains, according to Marshall, are moles, field mice, and the roots of trees: the first two may be kept under by traps or other devices: but the last enemy is not easily guarded against, except in the laying out of the drain, which should always, if possible, be kept distant from trees or woody plants of any description.

#### SECT. VIII. Of the Implements peculiar to Draining

4307. The tools peculiar to draining are chiefly of the spade kind: there are also boring instruments of different kinds.

4308. The *draining-scoop* (fig. 861-a, b, c,) is a crooked kind of tool made use of in some cases for clearing out the loose materials from the bottoms of drains. It is formed of different sizes and breadths, according to the drains and in working is drawn or pushed along the bottom.

4309. The *draining shovel* (d) is another sort of implement employed for the same purpose as the above. It is made with a crooked handle, and the edge of the shovel part is turned up, in order to prevent the materials from falling off.

4310. The *draining and leaf* (e) is an implement made use of with great benefit in scoring or cutting out the sward in forming drains.

4311. *Draining spades* (f & g) are made of different breadths, so as to follow each other and cut the drains narrow at the bottoms. A stiffer and pointed draining spade (g) is in general use, and a wooden one (h) is employed in peat soils.

4312. The *draining straw-twisting engine* is a machine of very simple construction, already described (2562) and capable of being readily removed, contrived for the purpose of twisting straw into ropes for the filling of drains.

4313. A variety of boring implements, including Good's and the post-borer, have been already described. (3507 to 2519)
